SELF-ASSESSMENT QUESTIONS

1. Which laboratory abnormalities are indicative of the secondary complications likely to occur in a patient with advanced CKD (stages G5 and ESKD)? *Decreases and increases are compared to the normal range for each parameter.*

   A. Increased phosphorus, potassium, active vitamin D

   B. Decreased bicarbonate, PTH, and potassium

C. Increased PTH and bicarbonate; decreased active vitamin D

D. Decreased phosphorus and PTH; increased potassium

E. Decreased active vitamin D; increased PTH and potassium

2. Increased hepcidin levels observed in patients with CKD result in a/an ___________ in iron release into plasma due to binding of hepcidin to ___________?

A. decrease; ferroportin

B. increase; ferroportin

C. decrease: unbound iron

D. increase; unbound iron

E. decrease; ferritin

3. Which IV iron agent is approved for higher dose administration and would allow an adult patient with CKD stage G5 to receive a total dose of 1 g at a single clinic visit?

A. Ferric gluconate (Ferrlecit)

B. Ferric derisomaltose (Monoferric)

C. Iron sucrose (Venofer)

D. Iron dextran (InFeD)

E. Ferric pyrophosphate citrate (Triferic AVNU)

4. A 45-year-old male with CKD stage G3b (eGFR of 42 mL/min/1.73 m^2) is seen in the nephrology clinic. His labs today show the following: Hb 8.5 g/dL (85 g/L; 5.28 mmol/L) (down from 10.5 g/dL [105 g/L; 6.52 mmol/L] 3 months ago), TSat 34% (0.34), serum ferritin 610 ng/mL (µg/L; 13.7 pmol/L). He reports feeling tired and less able to do his activities of daily living. Work up shows no signs of active bleeding. Should this patient be started on an erythropoietic stimulating agent (ESA) and what is the rationale?

A. Yes, his Hb is below 10 g/dL (100 g/L; 6.21 mmol/L) and the extent of decline indicates a high likelihood of needing a blood transfusion

B. Yes, an ESA is indicated to enhance his quality of life and decrease mortality risk

C. Yes, his Hb is below 12 g/dL (120 g/L; 7.45 mmol/L) and the goal is to normalize the Hb in non-dialysis CKD patients.

D. No, an ESA will not be effective since his iron indices are low and iron should be administered first

E. No, his Hb is above 8 g/dL (80 g/L; 4.97 mmol/L) and he has not had a large decline in Hb since his last visit

5. A patient with CKD stage G3b is to be started on oral ferrous sulfate for iron deficiency for at least 2 months. This patient should be instructed to take:

A. A 325 mg test dose and be observed for anaphylactic reactions

B. Iron between meals to increase absorption in the GI tract

C. At least 500 mg of elemental iron per day if tolerated

D. An antacid with iron to minimize the risk of GI adverse effects

E. Ferrous sulfate with at least 8 ounces of water to prevent GI adverse effects

6. A patient with CKD stage G5 is noted to be iron deficient and is prescribed a full course of IV iron (1-1.5 g total). She will receive the total dose of IV iron divided over 2 clinic visits (today and one week later). Which regimen is most appropriate to administer at each visit?

   A. Ferumoxytol 510 mg IV push over 5 minutes

   B. Iron dextran 25 mg test dose followed by infusion of 500 mg over 30 minutes

   C. Ferric carboxymaltose 750 mg infused over 30 minutes

   D. Ferric gluconate 500 mg infused over 30 minutes

   E. Iron sucrose 1 gram administered over 3 hours

7. Which statement provides an accurate description of an available erythropoiesis stimulating agent and the advantage of using this agent.

   A. Epoetin-alfa-epbx has a longer half-life than darbepoetin alfa and requires less-frequent dosing.

   B. Darbepoetin alfa has a longer half-life than methoxy PEG beta and requires less-frequent dosing.

   C. Darbepoetin alfa has a shorter half-life than epoetin-alfa and requires more frequent dosing.

   D. Methoxy PEG epoetin-beta has a longer half-life than epoetin-alfa and requires less-frequent dosing.

   E. Methoxy PEG epoetin-beta may be used in a fixed dose and does not require dose titration.

8. Which of the following agents would be preferred in a hemodialysis patient with ESKD, a PTH persistently above 700 pg/mL (ng/L; 75 pmol/L) and elevated calcium levels?

   A. Etelcalcetide

   B. Cholecalciferol

   C. Calcitriol

   D. Ergocalciferol

   E. Calcifediol

9. A patient with ESKD on hemodialysis (HD) has had a PTH of 500 pg/mL (ng/L; 54 pmol/L) for the past 3 months, a phosphorus of 7.4 mg/dL (2.39 mmol/L), a calcium of 9.8 mg/dL (2.45 mmol/L), and an albumin of 3 g/dL (30 g/L). She currently receives calcitriol 1 μg IV three times weekly with HD, calcium acetate 1334 mg three times daily with meals, and ergocalciferol 50,000 IU once weekly. Which of the following is most appropriate to control her CKD-MBD?

   A. Discontinue the calcium acetate and begin a two-month course of aluminum hydroxide with meals

   B. Increase the calcium acetate to 2001 mg with meals

   C. Increase the calcitriol dose to 1.5 μg IV three times weekly

   D. Change the calcium acetate to calcium carbonate

   E. Discontinue the calcium acetate and begin lanthanum carbonate

10. Which vitamin D agent is active as given and is most appropriate for a patient with ESKD requiring vitamin D to treat secondary hyperparathyroidism (PTH 800 pg/mL [ng/L; 86 pmol/L])?

A. Ergocalciferol

B. Cholecalciferol

C. Calcifediol

D. Calcitriol

E. 1-α Hydroxylase

11. Which of the following is a potential advantage of using ferric citrate as a phosphate-binding agent compared to other sevelamer carbonate in a non-dialysis CKD patient?

A. It is available in a powder formulation.

B. It is also approved for iron-deficiency anemia.

C. It is available as a chewable tablet.

D. It can be given intravenously or orally.

E. It does not cause stool discoloration.

12. Which strategy should be followed when converting a patient from cinacalcet to etelcalcitide?

A. The two therapies should overlap by 2 weeks to allow etelcalcitide time to reach steady state.

B. Wait at least 7 days after discontinuing cinacalcet prior to initiating etelcalcitide.

C. Wait at least 4 weeks after discontinuing etelcalcitide prior to initiating cinacalcet.

D. Cinacalcet may be initiated once etelcalcitide levels are undetectable.

E. A test dose of etelcalcitide should be administered to determine if the patient will tolerate therapy.

13. According to KDIGO guidelines, statin therapy is recommended for primary prevention of cardiovascular events in which of the following patients?

A. 60-year-old male with ESKD not previously on a statin.

B. 75-year-old female with ESKD and diabetes not previously on a statin.

C. 40-year-old male with CKD G3b with coronary artery disease.

D. 38-year-old female with CKD G2 and no cardiac risk factors.

E. Statins are recommended only for secondary prevention in patients with CKD.

14. Which statement most accurately describes what is known regarding cardiovascular disease (CVD) in patients with CKD?

A. There is a lower risk of CVD once a patient begins hemodialysis.

B. In general, survival is the same for a given CVD condition compared to patients without CKD.

C. Nontraditional risk factors for CVD in patients with CKD include proteinuria and anemia.

D. The prevalence of CVD decreases as CKD progresses from early- to later-stage CKD.

E. There is an abundance of evidence-based data to address treatment for most. cardiovascular diseases in patients with CKD since they are often included in the clinical trials.

15. Which is the most evidence-based treatment strategy for a patient with ESKD experiencing chronic CKD-associated pruritis?

    A. Difelikefalin to target kappa opioid receptors

    B. Paricalcitol to reduce parathyroid hormone to goal levels

    C. More frequent dialysis to remove histamine

    D. Diphenhydramine to inhibit histamine-induced allergic symptoms

    E. Topical corticosteroid therapy

SELF-ASSESSMENT QUESTION-ANSWERS

1. **E.** Common secondary complications beyond the main complications discussed in this chapter are listed in Table 63-1. Among them, choice is the only one that includes laboratory abnormalities consistent with advanced CKD. Decreased levels of active vitamin D and increased PTH are consistent with CKD-MBD (increased phosphorus is also anticipated). Hyperkalemia is also expected in a patient with advanced CKD. Other complications include anemia (indicated by a decreased hemoglobin) and metabolic acidosis (indicated by a decrease serum bicarbonate).

2. **A.** Hepcidin is a hormone produced in the liver and is the primary regulator of iron homeostasis. This hormone binds to and inhibits ferroportin that transports iron out of storage cells and into the circulation. Hepcidin levels are increased in patients with CKD and lead to decreased intestinal iron absorption, impaired iron recycling from macrophages, and decreased mobilization from hepatocytes.

3. **B.** Among the agents listed, ferric derisomaltose is the only agent approved for higher dose administration in patient with nondialysis CKD and offers the advantage of administering a full course of iron (1,000 mg) in one administration (see Table 63-4).

4. **A.** This patient meets the criteria for initiation of an ESA (Table 63-2) based on his currently Hb level of less than 10 g/dL (100 g/L; 6.21 mmol/L) and the rate of decline in this patient's Hb indicating that a further decline is likely. The iron indices are at goal so additional iron supplementation alone is not expected to correct his anemia. Option A is consistent with the criteria listed in Table 63-2.

5. **B.** Taking iron on an empty and avoiding agents that increase the pH of the GI tract is recommended to improve iron absorption. A test dose is required only for intravenous therapy with iron dextran. Increased fluid intake is not expected to alter tolerability of oral iron.

6. **C.** When iron is administered intravenously the main consideration is to avoid giving iron too rapidly in order to avoid adverse reactions (eg, hypotension, iron overload). Iron formulations differ in terms of the carbohydrate shell that surrounds iron and the rate at which iron is released. Ferric carboxymaltose, ferric derisomaltose, and ferumoxytol and agents that may be administered in a larger dose and at a faster rate compared to the smaller molecular weight compounds (iron sucrose, sodium ferric gluconate, and iron dextran). Of the options listed, only choice C follows the recommendations for the amount and rate of administration (see Table 63-4).

7. **C.** Available ESAs and the corresponding half-life for each are listed in Table 63-5. Methoxy polyethylene glycol (PEG) epoetin-beta has the longest half life and offer the option of less-frequent dosing. The starting dose is a weight-based dose and the dose titration is dependent on the rate of change in hemoglobin as with other ESAs.

8. **A.** Based on the persistently elevated PTH values, this patient meets criteria for vitamin D therapy and/or a calcimimetics based on KDIGO guidelines (see Table 63-6). Since the patient has hypercalemia, the best option now is a calcimimetic which lowers both PTH and calcium. Etelcalcetide is the only calcimimetic agent listed (cinacalcet is the other available agent). Vitamin D, particularly calcitriol, and the vitamin D analogs may contribute further to hypercalcemia. Etelcalcetide is administered intravenously at the end of dialysis and is a good option if nonadherence is a concern. Cinacalcet is an oral calcimimetic that would also be an option, but patient adherence with therapy would have to be considered.

9. **E.** This patient has a PTH within the target range of 2 to 9 times the upper limit of normal (using a general upper limit of 65 pg/mL [ng/L; 7 pmol/L), an elevated phosphorus and a corrected calcium of 10.4 mg/dL (2.60 mmol/L) which is at the upper limit of normal. The patient should continue to receive vitamin D with calcitriol or a vitamin D analog since the PTH has been within the target range. A phosphate binder is required based on the phosphorus

level, but a calcium-containing agent is not the best option given the high calcium levels. The best option is to minimize the risk of hypercalcemia by switching to a non-calcium containing agent such as lanthanum, iron-based binders, or sevelamer carbonate.

10. **D.** Calcitriol is the active form of vitamin D (1-25 dihydroxyvitamin D_3) and is the only agent on the list that is active as given. Ergocalciferol and cholecalciferol are nutritional vitamin D agents and require activation by the liver and the kidney. Calcifidiol is 25-hydroxvitamin D_3 (the precursor form of vitamin D) that requires activation by the liver. 1-α-Hydroxylase is not a vitamin D agent but is the enzyme responsible for converting vitamin D to the active form in the kidney.

11. **B.** Ferric citrate is an iron-containing phosphate binder approved for use as both a phosphate binder in patients with CKD receiving dialysis and for iron deficiency anemia in CKD patients not on dialysis. Clinical studies demonstrated a significant increase in iron indices (transferrin saturation and serum ferritin). This agent is only available in tablet form, not as a powder, and is not to be chewed. As an iron-containing agent, stool discoloration may occur.

12. **B.** If switching a patient from cinacalcet to etelcalcetide, then cinacalcet should be discontinued for at least 7 days prior to starting etelcalcetide. If switching patients from etelcalcetide to cinacalcet, etalcalcetide should be discontinued for at least 4 weeks prior to starting cinacalcet due to the long half-life of etalcalcetide.

13. **C.** Refer to the "Statins in CKD" section of the chapter and the KDIGO Lipid Guidelines. Options A and B are incorrect because adults with dialysis-dependent CKD should not be initiated on a statin. Option C is correct because adults aged 18 to 49 years not receiving dialysis should be initiated on a statin if they have known coronary artery disease. Option D is incorrect since this patient is not older 50 years and her eGFR is >60 mL/min/1.73 m^2 with no additional risk factors. Option E is incorrect as statins are indicated for primary prevention in certain types of CKD patients.

14. **C.** Proteinuria and anemia are among the nontraditional risk factors for cardiovascular disease in patients with advanced CKD. The other options are incorrect as patients with CKD have a higher mortality, have worsening risk of cardiovascular disease as kidney function declines, and have a higher mortality compared to patients without CKD. Most clinical trials exclude patients with advanced CKD and there is limited data for most cardiovascular diseases in this population.

15. **A.** The mechanism of CKD-associated pruritus is poorly understood. Pruritus has been associated with inadequate dialysis and elevated PTH, calcium, and phosphorus; however, these associations are inconsistent and their correction does not necessarily correlate with resolution of pruritus. Difelikefalin is a peripheral kappa opioid receptor agonist exerts antipruritic effects by means of activation of kappa opioid receptors on peripheral neurons and immune cells. This agent has been studied in HD patients and was approved for moderate-to-severe pruritus in hemodialysis patients.

Chapter 64: Hemodialysis and Peritoneal Dialysis

Kevin M. Sowinski; Mariann D. Churchwell

KEY CONCEPTS

KEY CONCEPTS

① Hemodialysis (HD) involves the perfusion of blood and dialysate on opposite sides of a semipermeable membrane. Solutes are removed from the blood by diffusion and convection. Excess plasma water is removed by ultrafiltration.

② Native arteriovenous (AV) fistulas are the preferred access for HD because of fewer complications and a longer survival rate. Venous catheters are plagued by complications such as infection and thrombosis and often deliver low blood flow rates.

③ Adequacy of HD can be assessed by the Kt/V and urea reduction ratio (URR). The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative minimum goal Kt/V is greater than 1.2 per treatment and the URR is greater than 65%.

④ During HD, patients commonly experience hypotension and cramps. Other more serious complications include infection and thrombosis of the vascular access.

⑤ Peritoneal dialysis (PD) involves the instillation of dialysate into the peritoneal cavity via a permanent peritoneal catheter. The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane. Solutes are removed from the blood across the peritoneum via diffusion and ultrafiltration. Excess plasma water is removed via ultrafiltration created by osmotic pressure generated by various dextrose or icodextrin concentrations.

⑥ Patients on PD are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges completed each day results in greater solute removal.

⑦ Peritonitis is a common complication of PD. Initial empiric therapy for peritonitis should include intraperitoneal antibiotics that are effective against both gram-positive and gram-negative organisms.

⑧ Nasal carriage of *Staphylococcus aureus* is associated with an increased risk of catheter-related infections and peritonitis. Prophylaxis with a topical antimicrobial agent (mupirocin 2% or polysporin triple ointment) applied to the catheter exit site after each dialysis session can reduce catheter-related infections.

BEYOND THE BOOK

BEYOND THE BOOK

Visit the National Institute of Diabetes and Digestive and Kidney Diseases website <https://www.niddk.nih.gov/health-information/kidney-disease/kidney-failure>. Review the information provided in the "Hemodialysis" and "Peritoneal Dialysis" links. Watch the video titled "What is Dialysis?" <https://www.youtube.com/watch?v=mi34xCfmLhw>. The video provides a brief description of hemodialysis and peritoneal dialysis. This website and video are useful to enhance student understanding of and potential treatments for end-stage kidney disease.

INTRODUCTION

The three primary treatment options for patients with end-stage renal disease (ESRD) are hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data System (USRDS) is the national system that "collects, analyzes, and distributes" data relating to patients with ESRD or Stage 5 chronic kidney disease (CKD) in the United States and releases these data yearly.[1] According to the 2020 USRDS, at the end of 2018, there were 785,883 patients in the United States with ESRD. Of whom, 62.7% were being treated with in-center HD, 1.6% home HD, 7.6% PD, and nearly 29.7% had a functioning kidney transplant. Each of these represent an increase on the actual number of patients in each treatment modality. In 2018, 131,636 new patients started therapy for ESRD. In 2018, the prevalence of ESRD was 3.4 times greater in Black patients than White patients. In addition, the percentage of Black patients treated with in-center HD is higher in Black people than White people.[1]

Since 1972, the cost of treating ESRD has been covered by Medicare. In 2015, Medicare fee-for-service spending for patients with ESRD was $49.2 billion, which make up approximately 7% of all Medicare claim costs. ESRD consumes a vastly disproportionate amount of resources as only 1% of Medicare patients have the disease. Although total spending for ESRD treatment continues to climb by 2.1% each year, per-patient spending (after adjusting for inflation) increased by only 1.1% in 2018.[1] The prevalence of ESRD continues to climb, reflective of reduced mortality and enhanced patient care. The two primary diagnoses and underlying etiologies of kidney disease for new patients with ESRD are diabetes and hypertension.[1] Chapter 62 provides a thorough discussion on the epidemiology of chronic kidney disease.

This chapter serves as a primer on the principles and practice of dialysis and the complications associated with the delivery of dialysis treatments. HD and PD as the modalities most commonly employed for the management of ESRD (see Chapter 61 for a discussion of the role of renal replacement therapies in the management of acute kidney injury). The pertinent factors that should be considered before the initiation of dialysis are described. The morbidity and mortality associated with HD and PD are compared, as these considerations may influence the dialysis method chosen by patients and clinicians. The variants of HD and PD are detailed, and the multiple types of vascular and peritoneal access used with each (ie, catheters and surgical techniques) are illustrated. The concept of dialysis adequacy for each modality is briefly reviewed. Finally, the clinical presentation of common complications of both dialytic therapies is presented, along with pertinent nonpharmacologic and pharmacologic therapeutic approaches. Information resources that describe the influence of CKD on patient's quality of life, as well as the patient perspective on dialysis and dialysis-related therapies, are presented to highlight the human consequences of chronic disease.

Morbidity and Mortality in Dialysis

Morbidity in patients receiving dialysis can be assessed in a number of different ways including the number of hospitalizations per patient-year, the number of days hospitalized per patient-year, or the incidence of certain complications. The number of all-cause hospital admissions, 1.58 hospitalizations per patient-year, has fallen in recent years from greater than 1.82 hospitalizations per patient-year in 2009. Trends in hospitalization demonstrate an increase in hospitalization as a consequence of infection and cardiovascular disease and a decrease in hospitalizations as a consequence of vascular access problems. Patients with a functioning kidney transplant have a lower rate of hospitalization and shorter length of stay. Hospitalizations are more frequent in women than men, and in White people than Black people, and the frequency and duration increase with age in both dialysis modality groups.[1]

The life expectancy of US dialysis patients is markedly lower than that of healthy subjects of the same age and sex. In dialysis patients older than 75 years, the risk of dying is greater than fourfold higher when compared to all Medicare patients not receiving dialysis.[1] Adjusted all-cause mortality is greater for dialysis patients compared with age-matched individuals. Greater than 50% of deaths in dialysis patients are cardiovascular related. In fact, those with CKD are more likely to die from cardiovascular disease before they reach ESRD. Infections, usually related to the dialysis access, are the second-most common cause of death in dialysis patients. Although mortality remains high in this patient population, the overall patient mortality rate has fallen among dialysis patients since 2009. The reductions are dependent on treatment type and are smallest for HD and greatest for transplantation. In the United States, only 58% of HD patients and 68% of PD patients are alive 3 years after ESRD diagnosis and initiation of dialysis treatment.[1]

In addition to high morbidity and mortality, a dialysis patient's quality of life is generally poor. For example, restrictions caused by thrice weekly HD and/or associated treatments have been shown to impact many areas of a patient's life. These include, but are not limited to, physical endurance, sex, employment, social life, and diet. Patients often complain of fatigue and fear of the unknown related to their disease and its progression. The PD patient or the home HD patient may have some freedom from these restrictions, but this freedom comes with its own constraints.

Indications for Dialysis

Since first published in 2002, The National Kidney Foundation's Kidney Disease Outcome Quality Initiative (KDOQI) has been the primary treatment guideline for CKD. Although the Kidney Diseases: Improving Global Outcomes (KDIGO) guidelines[2] published in 2013, the updated 2015 version of the KDOQI guidelines serves as the most up-to-date recommendations.[3] Planning for dialysis initiation should occur when a patient's kidney function declines to CKD stage 4 (estimated glomerular filtration rate [eGFR] below 30 mL/min/1.73 m^2).[3] Beginning the preparation process at this point allows adequate time for proper education of the patient and family and for the creation of a suitable vascular or peritoneal access. For patients choosing HD, a permanent arteriovenous (AV) access (preferably a fistula) should be surgically created when eGFR falls below 25 mL/min/1.73 m^2, serum creatinine is greater than 4 mg/dL (354 μmol/L), or 1 year prior to the anticipated need for dialysis.[4] The KDIGO and KDOQI guidelines provide recommendations for referral to a specialist in kidney care services and for planning for RRT. The recommendation for timely referral is for patients with progressive CKD in whom the risk of kidney failure within 1 year is greater than 10% based on validated risk prediction tools.[2]

The KDIGO guidelines and commentaries addressing them agree that the primary criterion for initiation of dialysis is the patient's clinical status, rather than a specific level of kidney function.[2,5] Namely, dialysis should be initiated when one or more of the following are present: signs or symptoms of kidney failure (eg, serositis, acid-base or electrolyte abnormalities, pruritis); inability to control volume status or blood pressure; a progressive deterioration in nutritional status or cognitive impairment. The guidelines suggest that these signs and symptoms are patient specific but tend to be evident once the patient's eGFR is in the range of 5 to 10 mL/min/1.73 m^2. The guidelines specifically indicate that RRT should be initiated to manage signs and symptoms and not to treat an arbitrary kidney function measurement.[2] The advantages and disadvantages of HD and PD are depicted in Tables 64-1 and 64-2, respectively. These factors, along with the patients' concomitant diseases, personal preferences, and support environments, are the principal determinants of the dialysis mode they will receive. The timing of dialysis initiation is a compromise between maximizing patient quality of life by extending the dialysis-free period while avoiding complications that will decrease the length and quality of dialysis-assisted life.[3]

TABLE 64-1

Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment.
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early.
3. Technique failure rate is low.
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis.
5. In-center hemodialysis enables closer monitoring of the patient.

Disadvantages

1. In-center hemodialysis requires multiple visits each week to the hemodialysis center, which translates into loss of patient independence.
2. Disequilibrium, dialysis-induced hypotension, and muscle cramps are common. May require months before the patient adjusts to hemodialysis.
3. Infections in hemodialysis patients may be related to the choice of membranes, the complement-activating membranes being more deleterious.
4. Vascular access is frequently associated with infection and thrombosis.
5. Decline of residual kidney function is more rapid compared to peritoneal dialysis.

TABLE 64-2

Advantages and Disadvantages of Peritoneal Dialysis

Advantages

1. Hemodynamic stability due to slow ultrafiltration rate.
2. Higher clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance.
3. Better preservation of residual kidney function.
4. Convenient intraperitoneal route for administration of drugs such as antibiotics and insulin.
5. Suitable for elderly and young patients who may not tolerate hemodialysis well.
6. Freedom from the “machine” gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis).
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron.
8. No systemic heparinization required.
9. Subcutaneous vs intravenous erythropoietin or darbepoetin may reduce overall doses and be more physiologic.

Disadvantages

1. Protein and amino acid losses through peritoneum and reduced appetite from continuous glucose load and sense of abdominal fullness predispose patients to malnutrition.
2. Risk of peritonitis.
3. Catheter malfunction, and exit-site and tunnel infection.
4. Inadequate ultrafiltration and solute clearance in patients with a large body size, unless large volumes and frequent exchanges are employed.
5. Patient burnout and high rate of technique failure.
6. Risk of obesity with excessive glucose absorption.
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain are more common than HD.
8. Extensive abdominal surgery may preclude peritoneal dialysis.
9. No convenient access for intravenous iron administration.

There is considerable debate in the literature regarding the mortality differences between HD and PD.[6–8] Most observational trials suggest that PD is associated with a survival advantage early in therapy, which wanes with increased treatment time. Prospective trials have reported conflicting results relative to efficacy of one modality over another. If there is a survival advantage for PD, the consensus is that the advantage is early in therapy and may not with continued therapy. Well-designed studies are extremely difficult to conduct in this population, and thus the question of superiority of one modality over the other is controversial and continues to be debated. Differences in outcomes may be related to a wide array of confounding factors, such as the dose of dialysis, baseline patient health status, physician bias in modality selection, patient compliance with dialysis and medication therapy, or other unknown factors. For example, healthier patients tend to be directed toward PD, and factors such as age, duration of dialysis, and comorbidities play an important role in the complex relationship between patient outcomes and mortality. Without clear distinction between modalities in terms of many important outcomes, the selection of the optimal therapy for a given patient is challenging. The selection of one modality over the other should be based upon patient motivation, desire, geographic distance from an HD unit, healthcare team preference, and patient education rather than survival advantages alone.

HEMODIALYSIS

Although HD was first successfully used in 1940, the procedure was not used widely until the Korean War in 1952. Permanent dialysis access was developed in the 1960s, which allowed routine use of HD in patients with ESRD. Subsequent decades brought advances in dialysis technology, including the introduction of more efficient and biocompatible dialyzer membranes and safer techniques. HD is the most common type of renal replacement therapy for patients with ESRD.

Principles of Hemodialysis

① Hemodialysis consists of the perfusion of blood and a physiologic solution on opposite sides of a semipermeable membrane. Multiple substances, such as water, urea, creatinine, potassium, uremic toxins, and drugs, move from the blood into the dialysate, by either passive diffusion or convection as the result of ultrafiltration. Diffusion is the movement of substances down a concentration gradient. The rate of diffusion depends on the difference between the concentration of the solute in blood and dialysate, solute characteristics, ie, size, water solubility, and charge, the dialyzer membrane composition, and blood and dialysate flow rates. Diffusive transport is rapid for small solutes but decreases with increasing molecular size. Other important diffusive solute transport factors include the membrane thickness, porosity, and the steric hindrance between the membrane pores and solute. Ultrafiltration is the movement of water across the dialyzer membrane because of hydrostatic or osmotic pressure and is the primary means for removal of excess fluid. Convection occurs when dissolved solutes move across a membrane with water transport. This occurs only if the pores in the dialyzer are large enough to allow them to pass along with water. Convection can be maximized by increasing the hydrostatic pressure gradient across the dialysis membrane or by using a dialyzer that is more permeable to water transport. Diffusion and convection can be controlled independently, and thus, a patient's HD prescription can be individualized to attain the desired degree of solute and fluid removal.[9]

Hemodialysis Access

② Obtaining and maintaining access to the circulation has been a challenge for long-term use and success of HD. Permanent access to the circulation may be accomplished by several techniques, including the creation of an AV fistula, an AV graft, or by venous catheters (Fig. 64-1).[10] As shown in Fig. 64-1, the native AV fistula is created by the anastomosis of a vein and artery (ie, the radial artery to the cephalic vein or the brachial artery to the cephalic vein). The native AV fistula has many advantages including providing the longest survival time of all blood-access devices and the lowest rate of complications such as infection and thrombosis. Patients with fistulas have increased survival and lower hospitalization rates compared to other HD patients. Finally, AV fistulas are the most cost-effective in terms of placement and long-term maintenance. Ideally, the most distal site (the wrist) is used to construct the first fistula; it is the easiest to create, and in the case of access failure, more proximal sites on the arm are preserved for later use. Unfortunately, fistulas require at least 1 to 2 months to mature before they can be routinely utilized for dialysis. Creation of an AV fistula, however, may be difficult in elderly patients and in patients with peripheral vascular disease, which is a particularly common comorbidity in patients with diabetes.

FIGURE 64-1

The predominant types of vascular access for chronic dialysis patients are (*A*) the arteriovenous fistula and (*B*) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft (depicted in green) is between the brachial artery and the basilic or cephalic vein. The flow of blood may be diminished in the radial and ulnar arteries since it preferentially flows into the low-pressure graft.

Synthetic AV grafts, usually made of polytetrafluoroethylene, are another permanent AV access option. These grafts require 2 to 3 weeks before they can be routinely used. Their primary disadvantages are shorter survival of the graft, and higher rates of infection and thrombosis. The least-desirable and least permanent HD access option involves the placement of a central venous catheter. Venous catheters can be placed in the femoral, subclavian, or internal jugular veins. Their main advantage is that they can be used immediately, and they are often used in small children, diabetic patients with severe vascular disease, the morbidly obese, and patients who have no viable sites for permanent AV access. Late referrals to a nephrology specialist for HD initiation and delayed placement of a more appropriate long-term access contribute to the use of venous catheters in chronic HD patients. The major problem with all venous catheters is that they have shorter survival and are more prone to infection and thrombosis than either AV grafts or fistulas. Furthermore, some catheters are not able to provide adequate blood flow rates, which may limit the deliverable dose of dialysis.[10,11] Regardless, tunneled dialysis catheters are used frequently because of the ease of insertion, pain-free dialysis needle placement and availability for immediate use. They are, however, associated with increased morbidity, mortality, and cost.

Hemodialysis Procedures

The HD system consists of an external vascular circuit through which the patient's blood is transferred in sterile tubing to the dialyzer via a mechanical pump (Fig. 64-2).[10] The patient's blood then passes through the dialyzer on one side of the semipermeable membrane and is returned to the patient. The dialysate solution, which consists of purified water and electrolytes, is pumped through the dialyzer countercurrent to the flow of blood on the opposite side of the semipermeable membrane. In most cases, systemic anticoagulation (usually unfractionated heparin in the United States) is used to prevent blood clotting in the HD circuit tubing. The process of dialysis results in the removal of metabolic waste products, medications, and water and replenishment of body buffers, such as acetate and bicarbonate.

FIGURE 64-2

In hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. An anticoagulant is administered to prevent clotting in the dialyzer. The dialysate is pumped at a rate of 500 to 800 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment.

Hemodiafiltration (HDF), another variant of traditional HD, enhances convective solute and water transport in addition to diffusive clearance to a much greater extent than high-flux HD.[10,12,13] When fluid losses exceed those desired for the patient, an IV infusion referred to as replacement fluid may be administered. HDF may improve outcomes due to its ability to remove middle molecular weight uremic solutes more efficiently than the other HD variants. HDF improves survival compared to conventional HD.[13,14] Preliminary information suggests that HDF enhances clearance of phosphate, beta-2 microglobulin, and pro-inflammatory solutes. This procedure is not used extensively in the United States. Barriers to its use are the high cost and logistic issues associated with providing the fluid replacement needs.

Dialyzers are made up of a polyurethane container containing hollow fibers which are suspended in dialysate. These hollow fibers, or dialysis membranes, are made up of three substances, unmodified cellulose (cuprophan), substituted cellulose (cellulose acetate), and cellulosynthetic materials. The permeability of these membranes varies and are divided into three general types: low flux, high efficiency, and high flux. Low-flux and high-efficiency membranes have small pores that limit clearance to relatively small molecules (size less than or equal to 500 daltons) such as urea and creatinine and are utilized for less than 20% of chronic HD procedures.[10] High-flux membranes are now used in the vast majority of patients because they are capable of removing high-molecular-weight endogenous substances, such as β2-microglobulin, and medications such as vancomycin.[10] The primary reason for using high-flux membranes is that clearance of water as well as low- and high-molecular-weight substances is much greater, allowing for shorter treatment times. To maximize the clearance capacity of high-flux dialyzers, the blood flow rates should be 400 to 600 mL/min, and dialysate flow rates greater than 500 mL/min, which necessitates strict controls and active monitoring of the rate of fluid removal. Typically, these dialyzers are composed of polysulfone, polymethylmethacrylate, polyamide, cellulose triacetate, and polyacrylonitrile.[10]

HD is usually prescribed as three sessions per week for 3 to 5 hours/session. These sessions are usually performed in “in-center” dialysis units. This is a large time commitment for any patient undergoing HD and results in substantial loss of control over their life. Several alternatives to this type of HD have been explored in an effort to balance dialysis adequacy with patient outcomes and quality of life. These alternatives include procedures that increase dialysis frequency, enhance dialysis duration, or both.[15–18] Examples are as follows: (1) frequent HD (5-7 sessions/week), which can be frequent short (less than 3 hours/session), frequent standard (3–5 hours/session), or frequent long sessions (longer than 5 hours/session); (2) long HD (more than 5 hours/session given 3-7 times/week, which can be long thrice weekly (administered either at night or during the day), long every other night (administered at night), and long frequent (administered at night 5-7 nights/week). Many of these alternatives are suggested to be associated with improved survival.[16–18] For example, in-center, thrice weekly HD was associated with a higher risk of the composite outcome of death, left-ventricular mass, and change in health composite score than in-center six times per week HD.[19] Intensive dialysis has been associated with reductions in left-ventricular mass and improved blood pressure control, both surrogates for improved cardiovascular outcomes, and improved phosphate removal. Lastly, and perhaps most importantly, these procedures are associated with a reduction in dialysis-related symptoms and improved quality of life.[16–18] Despite the perceived advantages and more frequent use in other countries such as New Zealand and Canada, the use of home HD is uncommon, albeit increasing in use in the United States, still less than 2% of dialysis patients receiving HD care at home at the end of 2018.[1] Potential obstacles to home HD include patient factors (eg, lack of self-efficacy, fear of self-cannulation, fear of catastrophic event, and fear of lack of quality care) and a lack of awareness of the availability of this type of dialysis. Finally, there are suggestions that patients receiving intensive dialysis may be at higher risk of access infections and need for vascular access procedures. Further clinical trials are needed to elucidate the role of these types of dialysis therapy. The 2015 KDOQI guidelines provide suggestions and/or recommendations that all patients be offered short frequent HD as an alternative to standard HD in addition to providing patients with information about the potential risk associated with them.[3]

Adequacy of Hemodialysis

The optimal dose of HD, the patient’s dialysis prescription, is that amount of therapy above which there is no cost-effective increment in the patient’s quality-adjusted life expectancy. The two primary goals of the dialysis prescription are to achieve the patient’s dry weight and the adequate removal of endogenous waste products such as urea. Dry weight is the target post-dialysis weight at which the patient is normotensive and free of edema. Measurement of urea removal, while imperfect, is the typical method used to quantify dialysis adequacy. Urea removal reflects the “delivered dose” of dialysis and is utilized as the surrogate for removal of other toxins.

The delivered or desired dose of dialysis in terms of solute removal can be expressed as the urea reduction ratio (URR) or the *Kt/V* (pronounced “K-T-over-V”). The URR is a simple concept and is easily calculated as follows:

$$\mathrm{URR} = \frac{\text{Predialysis BUN–Postdialysis BUN}}{\text{Predialysis BUN}} \times 100.$$

URR=Predialysis BUN–Postdialysis BUNPredialysis BUN×100.

The URR is frequently used to measure the delivered dialysis dose; however, it does not account for the contribution of convective removal of urea. The *Kt/V* is a unitless index based on the dialyzer clearance of urea (*K*) in L/h multiplied by the duration of dialysis (*t*) in hours, divided by the urea distribution volume of the patient (*V*) in liters.[10] The *Kt/V* is thus the fraction of the patient’s total body water that is cleared of urea during a dialysis session. Urea kinetic modeling, using computer software, is the optimal means to calculate the *Kt/V*.[10] An in-depth discussion of the pros and cons of various methods of calculating and interpreting *Kt/V* is beyond the scope of this chapter. The reader is referred to other sources for more in-depth information.[10]

③ For patients who receive thrice weekly HD, KDOQI recommends that the minimally adequate delivered dose of dialysis is a *Kt/V* of 1.2 (equivalent to an average URR of 65%).[3] To achieve this goal, the recommended target prescribed *Kt/V* is 1.4 (equivalent to an average URR of 70%).[3] For patients who receive HD on a schedule other than thrice weekly, the KDOQI suggests a target standard *Kt/V* of 2.3 volumes/week with a minimum delivered dose of 2.1. Lower doses of dialysis treatment are thought to be associated with increased morbidity and mortality. Many nephrologists believe that even greater doses of dialysis would have positive outcomes in dialysis patients, and so the average dose of dialysis has been increasing in the United States although the evidence for this is not strong. The results of HEMO study, a prospective, randomized trial that assigned patients to either standard (*Kt/V* = 1.25) or high-dose (*Kt/V* = 1.65) dialysis with high-flux or low-flux membranes, revealed that the risk of death was similar in both the standard and high-dose therapy and the low- and high-flux groups. Thus, there is no benefit in increasing the dose of dialysis above the current recommendations. The HEMO study only enrolled patients who were on traditional thrice-weekly dialysis, so the applicability of these findings to patients on more intensive regimens such as daily or nocturnal HD regimens remains to be determined. However, intensive HD regimens may result in better control of blood pressure, anemia, phosphate, and sleep apnea.[15] In those relatively few patients who are below the adequacy goal, the deficiency may be related to patient compliance with the dialysis prescription (ie, ending dialysis early) or low blood flow rates caused by access stenosis or thrombosis, or due to the use of catheters. Adequate dialysis may not be achieved in some patients despite compliance and sufficient blood flow. For these patients, there are two options to increase urea clearance: use a larger membrane or increase the treatment time.

Complications of Hemodialysis

④ HD is a life-extending therapy for patients with kidney failure but HD is associated with short- and long-term complications. Complications associated with HD can decrease the efffectiveness of therapy, quality of life and life expectancy. This chapter discusses complications that occur during an HD session (intradialytic) and complications associated with vascular access.

Hemodialysis Procedure Complications

The most common complications that occur during HD include hypotension, hypertension, cramps, nausea and vomiting, headache, chest pain, back pain, and fever or chills.[20] Table 64-3 lists these complications and their etiology and predisposing factors.

TABLE 64-3

Common Complications During Hemodialysis

	Incidence (%)	Etiology/Predisposing Factors
Hypotension	20-30	Hypovolemia and excessive ultrafiltration
		Antihypertensive medications prior to dialysis
		Target dry weight too low
		Diastolic dysfunction
		Autonomic dysfunction
		Low calcium and sodium in dialysate
		High dialysate temperature
		Meal ingestion prior to or during dialysis
Hypertension	5-15	Plasma sodium concentration
		Intravascular volume
		Dialytic removal of antihypertensive medications
		Activation of the Renin Angiotensin Aldosterone system
Cramps	5-20	Muscle hypoperfusion due to ultrafiltration and hypovolemia
		Hypotension
		Electrolyte imbalance
		Acid–base imbalance
Nausea and vomiting	5-15	Hypotension
		Dialyzer reaction
Headache	5	Disequilibrium syndrome
		Caffeine withdrawal due to dialysis removal
Chest and back pain	2-5	Unknown
Pruritus	5	Inadequate dialysis
		Skin dryness
		Secondary hyperparathyroidism

		Abnormal skin concentrations of electrolytes
		Histamine release
		Mast cell proliferation
Fever and chills	<1	Endotoxin release; infection of dialysis catheter

Data from Reference 10.

Intradialytic hypotension (IDH) as defined by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) is a decrease in systolic blood pressure by ≥20 mm Hg or a decrease in mean arterial pressure (MAP) by 10 mm Hg. A patient with IDH may experience abdominal discomfort, yawning, sighing, nausea, vomiting, muscle cramps, restlessness, dizziness or fainting, and anxiety. A decrease in BP can increase the risk of vascular access thrombosis, induce a cardiac arrhythmia, or predispose a patient to a coronary or cerebral ischemic event. Hypotension during HD can decrease the effectiveness of a dialysis session resulting in a lower Kt/V_{urea}.[21] A systolic blood pressure <90 mm Hg has been associated with increased mortality.[22]

A primary cause of IDH is related to the rate and amount of fluid removed during[10,23] typical HD treatments, although other causes, as listed in Table 64-4, may also play a role.[10,23] Symptoms such as nausea and cramping are often present during acute hypotensive episodes. The replacement of acetate with bicarbonate as the dialysate buffer, the use of volumetric ultrafiltration controllers, and individualized or modeled dialysate sodium concentrations have helped reduce the incidence of IDH. Sodium modeling uses a higher initial dialysate sodium concentration (145-155 mmol/L [mEq/L]) and tapers sodium concentration down (135-140 mmol/L [mEq/L]) over the dialytic session. Dialytic treatment modifications such as sodium individualization or modeling may decrease post-HD thirst and subsequent intradialytic weight gain. This modification may decrease the need for aggressive dialytic fluid removal and the incidence of IDH.[24-26]

TABLE 64-4

Management of Hypotension

Acute treatment	Place patient in Trendelenburg position
	Decrease ultrafiltration rate
	Give 100-200 mL bolus of normal saline intravenous
	Give 10-20 mL of hypertonic saline (23.4%) intravenous over 3-5 minutes
	Give 12.5 g mannitol
Prevention	
Nonpharmacologic	Accurately set “dry weight”
	Use steady constant ultrafiltration rate
	Keep dialysate sodium >serum sodium
	Lower dialysate temperatures
	Bicarbonate dialysate
	Avoid food before or during hemodialysis
Pharmacologic	Midodrine 2.5-10 mg orally 30 minutes before hemodialysis (start at 2.5 mg and titrate)
	Droxidopa 100-600 mg orally 1 hour before hemodialysis (start at 100 mg and titrate up to 600 mg)
	Other options (limited evidence):
	Levocarnitine 20 mg/kg IV after hemodialysis
	Sertraline 50-100 mg daily
	Fludrocortisone 0.1 mg before hemodialysis
	DDAVP 1-2 intranasal sprays (150 µg/spray)
Counsel patients	Administer antihypertensive medications in the evening or after hemodialysis
	Minimize intradialytic weight gain by decreasing salt content in their diet

Intradialytic or post-HD hypertension can occur in 5% to 15% of patients receiving HD and may increase post-HD fatigue and the risk of cardiovascular and all-cause mortality.[27] Underlying causes include, not achieving post-HD dry weight goal, over-estimation of dry weight, dialytic removal of antihypertensive medications, or the activation of the renin-angiotensin system secondary to abrupt hypovolemia.[28]

Skeletal muscle cramps complicate 5% to 20% of HD treatments. Although the pathogenesis of cramps is multifactorial, plasma volume contraction and decreased muscle perfusion caused by excessive ultrafiltration are frequently the initiating events.[10] Pruritus may increase in severity during the HD treatment and is a complication of CKD. The management of pruritus is discussed in Chapter 63.

Vascular Access Complications

The most common vascular access complications in patients receiving HD are thrombosis and infection. The highest occurrence of complications is found in patients with a central venous catheter (CVC) compared with those with an AV graft or AV fistula.[10,29] A majority of patients initiate HD with a central venous CVC (80.8%) of those patients 65.2% did so without a maturing AV fistula or graft (65.2%). In prevalent patients receiving HD, 82.4% had either an AV fistula or graft.[1] The maintenance of vascular access patency is critical for patients receiving HD. Predisposing factors are often described using Virchow's triad of blood flow stasis, hypercoagulability, and endothelial injury. An aneurysm or stenosis of an AV fistula, graft or surrounding vasculature generally require a surgical intervention. Several pharmacologic therapies have been evaluated to maintain vascular access patency but results are conflicting.[30] Vascular access stenosis can contribute to decreases in blood flow (blood flow <300 mL/min) and increase the risk of thrombus formation within the access. A decrease in blood flow through the access can occur abruptly, or over days to weeks or intermittently and may require ultrasound, venography, or computed tomography scans for a definitive diagnosis.[29,30] Catheter-related thrombosis can form either inside (intrinsic) or outside (extrinsic) the catheter. An occlusion can form within the lumen at the tip or develop a fibrin sleeve around the catheter where this fibrin sleeve can serve as a nidus for infection and ultimately require catheter removal.[31,32]

Infection is a leading cause of mortality in HD patients.[1] The risk of sepsis-related death is 100 times greater in patients receiving HD than the general population, and those with an indwelling catheter have the highest risk.[32] A comparison of patients receiving HD with a catheter compared to those without a catheter found a higher rate of bloodstream infections in patients with a catheter.[33] An examination of the United States Renal Data System identified patients initiating HD with a central venous catheter (CVC), AV fistula or graft from 2006 through 2014 who developed sepsis. The highest rate of sepsis was found in patients with a CVC (31.2%) followed by an AV graft (30.6%) and an AV fistula (22.9%, $P < 0.001$).[34]

The National Healthcare Safety Network (NHSN) dialysis event surveillance report found that 69.8% of access-related blood stream infections (ARBSIs) were in patients with an indwelling CVC.[35] The most prevalent pathogens for blood stream infections (BSIs) were gram-positive (64%) followed by gram-negative (35%) and Candida species (0.2%). The most frequently isolated micro-organisms in ARBSIs were as follows: *S. aureus* (31.8%), *S. epidermidis* (15.6%), coagulase-negative staphylococcus (9.7%), *E. faecalis* (4.9%), and *E. coli* (2.9%). The incidence with methicillin-resistant *S. aureus* (39.5%) and cephalosporin-resistant *E. coli* (17.8%) organisms were highest in patients with a CVC.[35]

Catheter-related infections can develop at the insertion site, hub, or both. The infection source for long-term catheters such as a tunneled cuffed catheter is usually the hub where bacteria can enter the blood leading to a BSI.[29,32] Overall, HD access with a catheter is associated with higher rates of bacteremia, osteomyelitis, septic arthritis, endocarditis, thrombus, and death, as well as increased treatment costs compared with an AV fistula or AV graft.[36]

Complications of CKD

Patients receiving HD are likely to have at least one additional comorbid disease such as diabetes, hypertension, cardiovascular disease, or obesity (BMI greater than or equal to 30 kg/m^2 and older age, greater than or equal to 60). The pharmacotherapy management of most CKD complications and comorbid diseases that persist in patients receiving HD are discussed in Chapter 63. The daily medication burden for HD patients is one of the highest for any chronic disease state. The pill burden in HD patients was reported as an average of 15.1±7.6 pills/day of which phosphate binder medications accounted for 6.44±4.78 pills/day.[37] Adherence to phosphate binder regimens is reported to be 43% in US patients receiving dialysis. Patients taking more than the average pills/day of phosphorus binders were more likely to miss a dose than patients taking less than the average pills/day. The increased pill burden is associated with a lower quality of life in patients receiving dialysis.[38]

Management of Hemodialysis Complications

The management of HD complications is discussed in this section. The most common causes of HD complications and appropriate management are reviewed.

Hypotension

Acute management of intradialytic hypotension (IDH) includes decreasing the ultrafiltration rate or stopping ultrafiltration, placing the patient in the Trendelenburg position, lowering the dialysate temperature, modifying dialysate electrolyte concentrations, and/or administering normal or hypertonic saline.[23,39,40] IDH may not occur during each HD session and a patient's response to therapeutic modifications can be variable, which could necessitate modification of their HD prescription. Patients with IDH will need a careful review of all medications including antihypertensive medications. Evaluation should consider the timing of antihypertensive medication administration and may require adjustments to medications administered the day prior to and the day of HD therapy.[23] Patients with IDH should be counseled to take their blood pressure medications after HD and avoid the consumption of food during HD.

IDH is often due to an insufficient cardiac response to reduced circulating blood volume: which may occur aggressive ultrafiltration is required to restore dry weight. Most treatments for IDH are directed toward restoring or maintaining adequate blood vessel perfusion in these patients. One approach is to limit interdialytic weight gain (IDWG) that may decrease the rate and volume of fluid removal during HD. Patients are counseled to limit dietary salt intake especially hidden sodium in processed foods. A reduction in dietary sodium could decrease a patient's thirst and subsequent fluid intake.[10] Another approach, decreasing the dialysate temperature to 36.5°C (97.7°F) may help reduce core body temperature, which can decrease vasodilation.[30,41] If nonpharmacologic interventions are not adequate to prevent or reduce the incidence of symptomatic IDH, then pharmacologic interventions should be considered (see Table 64-4).

Oral midodrine (5-10 mg) given two to three times daily can increase blood pressure in patients receiving HD with chronic hypotension. Midodrine, an alpha-1 adrenergic agonist, can also be administered 30 minutes prior to initiating HD to increase intradialytic blood pressure. It is rapidly absorbed in the gastrointestinal tract and will begin to increase blood pressure within 60 minutes. Midodrine's half-life during HD can be less than 2 hours but on nondialysis days it is approximately 10 hours. HD will remove the prodrug and metabolite of midodrine which contributes to the drug's decreased half-life during HD. It is important to note that the effects of midodrine are probably best in patients with hypotension related to autonomic dysfunction. Patients with peripheral vascular disease should be monitored for digital or lower limb ischemia.[42]

Droxidopa is an oral synthetic amino acid analog metabolized by the catecholamine pathway to norepinephrine, resulting in vasoconstriction of peripheral veins and arteries. Droxidopa is FDA approved for neurogenic orthostatic hypotension. Droxidopa was studied in patients with a history of IDH that were randomized to receive droxidopa 400 mg, 600 mg, or placebo 1 hour prior to HD. The patients receiving droxidopa when compared to placebo had a lower rate of early HD termination due to IDH. Gastrointestinal disorders were the most frequent adverse effect reported in the treatment groups.[43]

Fludrocortisone is a potential agent for symptomatic IDH, including patients with an inadequate response to midodrine. It increases blood pressure through several mechanisms including enhancing blood vessel sensitivity to circulating catecholamines. Fludrocortisone dosing for orthostatic hypotension generally ranges from 0.1 mg to 1.0 mg/day but IDH dosing has not been determined. A case report described a patient receiving HD with IDH and a decreased response to midodrine that resulted in early termination of HD sessions. Fludrocortisone 0.2 mg was administered with 10 mg of midodrine 30 minutes prior to the start of HD. Prior to initiating fludrocortisone, 6 out of 45 HD sessions were terminated early but after fludrocortisone initiation, no HD sessions were terminated early in the subsequent 45 HD sessions.[44] The use of fludrocortisone may be beneficial in select patients with IDH but adverse effects such as sodium and water retention could increase edema in patients with congestive heart failure.

The treatment of IDH with levocarnitine, sertraline, and intranasal desmopressin acetate (DDAVP) have been reported to improve IDH. Administration of levocarnitine (20 mg/kg IV at the end of each HD session) may reduce hypotensive episodes, particularly in patients with carnitine deficiency.[45] High cost and limited efficacy precludes a strong recommendation for routine levocarnitine use. The administration of sertraline 50 mg daily titrated to 100 mg daily after 1 week improved systolic and diastolic blood pressure in a small trial.[46] Sertraline 50 mg was administered daily to patients receiving HD, but sertraline did not increase in post-HD blood pressure.[47] The mixed results do not support routine sertraline administration for hypotension. Overall, the use of DDAVP increased post-HD blood pressure and decreased the incidence of IDH.[48] These medications have limited clinical evidence and should be used with caution in patients receiving HD with IDH. Overall, the best evidence for an oral pharmacological treatment of IDH is with midodrine. Alternative agents have been studied but the evidence is limited for each of these agents as many of the studies had a small sample size and did not have a placebo control.

Hypertension

An elevated blood pressure in a patient prior to receiving HD is often attributed to volume expansion. A decline in blood pressure is expected during and after HD and improves survival, but a dramatic increase or decrease in blood pressure during or after HD decreases overall survival.[49] An increase in blood pressure of > 10 mm Hg either during or post-HD may require a change in the delivery of a HD session, antihypertensive medications or adjustments to the timing of medication administration.[28] Although the underlying mechanism may be multifactorial, antihypertensive medication dialyzability could play a role in HD-related increases in blood pressure.[50] HD enhances the clearance of metoprolol, atenolol, and angiotensin-converting enzyme inhibitors (ACE-Is). An angiotensin receptor blocker (ARB), carvedilol or amlodipine are minimally removed during HD and may be an option in patients experiencing a rise in blood pressure during or post-HD. Antihypertensive medication regimes need to be individualized based on a patient's comorbid conditions and risk of HD-related blood pressure changes. A retrospective cohort examined patients with heart failure receiving HD and either taking a daily beta-blocker (carvedilol, bisoprolol, or metoprolol CR/XL) or those patients not taking a daily beta-blocker. Patients receiving either carvedilol, bisoprolol, or metoprolol had lower all-cause mortality at 5 years.[51] However, in patients at risk of IDH, a large retrospective study found an increased rate of IDH and risk of all-cause mortality in patients taking carvedilol compared to metoprolol.[52] Initiation of any antihypertensive medication in patients at high-risk should be followed with close monitoring pre- and post-HD in addition to during HD. One small study found an improvement in patients with intradialytic hypertension when low-dose carvedilol (6.25 mg twice daily) was initiated and titrated as tolerated.

Muscle Cramps

The cause of muscle cramps in patient receiving HD may be multi-factorial and include aggressive removal of fluid and electrolyte imbalances. Nonpharmacologic interventions related to dialytic therapy may help alleviate muscle cramps. These measures include adjusting the ultrafiltration rate to avoid hypotension, volume contraction, or hypoosmolality. Other methods to reduce muscle cramps, including compression devices, moist heat, massage, exercise, stretching, or muscle flexing, should be considered first to minimize adverse consequences (Table 64-5).[10,23]

TABLE 64-5

Management of Cramps

Acute treatment	Give 100-200 mL bolus of intravenous normal saline
	Give 10-20 mL of intravenous hypertonic saline (23.4%) over 3-5 minutes
	Give 50 mL of 50% intravenous glucose (nondiabetic patients)
Prevention	
Nonpharmacologic	Accurately set "dry weight"
	Keep dialysate sodium >serum sodium
	Stretching exercises, massage, flexing, or compression devices
Pharmacologic	Vitamin E 400 international units at bedtime.
	Quinine 324 mg daily (second-line therapy)

Pharmacologic interventions include increasing the magnesium concentration in dialysate, supplementation with oral magnesium, vitamin E, or vitamin C or a trial of gabapentin or quinine. Vitamin E and quinine can reduce the incidence of muscle cramps.[53,54] Quinine is associated with temporary sight and hearing disturbances, thrombocytopenia, or gastrointestinal distress. Quinine is FDA approved for malaria only and the FDA has warned against the off-label use of quinine for muscle cramps.[55]

In a small prospective study of patients receiving HD with at least six episodes of intradialytic muscle cramps in the 30 days prior to enrollment, patients received either placebo or gabapentin 300 mg three times a week administered 5 minutes prior to HD. After 1 month, patients experienced less episodes of muscle cramps in the treatment arm.[56] Both vitamin E (400 mg) and vitamin C (250 mg) reduced the frequency of cramps in patients receiving dialysis.[57] The combination of these two drugs had an additive effect. Although these data further strengthen the case for vitamin E and vitamin C long-term therapy must be used with caution. Doses of vitamin E greater than 400 U/day have been reported to increase mortality and high doses of vitamin C increase the risk of oxalate accumulation and developing oxalosis. Pharmacologic interventions to diminish muscle cramps are limited and vitamin E has the strongest evidence-based efficacy and safety profile.

Vascular Access Thrombosis

Vascular access patency is key to maintaining effective dialytic therapy for patients receiving HD. Multiple pharmacologic agents have been studied including oral and intravenous anticoagulant and antiplatelet agents and intravenous thrombolytic agents to assess their clinical value.

The efficacy of oral antiplatelet therapy for the prevention of vascular access thrombosis has not been well established. Studies in patient receiving HD have shown and increased risk of bleeding with minimal benefit in maintaining vascular access patency. Therapy with antiplatelet agents should be individualized based on the patient's risk factors and co-morbidities.[30] A meta-analysis of randomized controlled trials for the prevention of vascular access failure identified nine trials assessing antiplatelet therapy and dialysis access patency in AV fistula ($n = 6$) and graft ($n = 3$).[58] This analysis found a lower rate of thrombosis or patency failure in patients with an AV fistula taking either aspirin, ticlopidine, or clopidogrel for up to 6 months (RR, 0.49; 95% CI, 0.30–0.81). In patients with an AV graft, there was no benefit with any of these antiplatelet therapies (RR, 0.94; 95% CI, 0.80-1.10). A post-hoc analysis identified that patients receiving aspirin prior to AV graft placement had improved graft patency but not graft survival.[59] An observational study in patients undergoing surgery for the creation of a HD-related vascular access examined primary patency at 12 months and compared antiplatelet therapy (aspirin or a platelet adenosine diphosphate receptor ($P2Y_{12}$) inhibitor) versus no antiplatelet therapy. There was no difference in primary patency between antiplatelet versus no antiplatelet therapy in patients receiving an AV fistula. There was a significant increase in primary patency in patients receiving and AV graft and antiplatelet therapy ($P = 0.04$). In hospital bleeding was assessed but long-term bleeding and bleeding risk were not reported and these results need to be interpreted with caution as previous studies have found an increased risk of bleeding with $P2Y_{12}$ inhibitors[60] Overall, the studies have reported conflicting results, and patients with an AV graft taking antiplatelet therapy prior to a procedure may have some benefit but initiating aspirin post-surgery may increase the risk of thrombosis.

The use of anticoagulation to maintain vascular access patency remains controversial with some trials suggesting an increase in morbidity and mortality.[61,62] Patients receiving HD generally require a lower dose of anticoagulation and are at a much higher risk of a major hemorrhagic event.[61,62] An examination of patients receiving a new AV fistula or graft from 2011 to 2019 were identified in the Vascular Quality Initiative database. Patients received either no anticoagulation or anticoagulation (warfarin, dabigatran, or rivaroxaban) post-procedure. At 6 months post procedure patients who received anticoagulation had a higher rate of wound infections (3.8% vs 2.3%) and a lower rate of access patency (84.3% vs 85.7%) compared to patients receiving no anticoagulation.[63] The decision to initiate anticoagulation in patients receiving HD should be individualized for a patient's comorbid diseases and bleeding risk.

The effect of fish oil supplementation, a combination of eicosapentaenoic acid (EPA) 400 mg and docosahexaenoic acid (DHA) 200 mg, on AV graft patency for 12 months after graft placement revealed that the loss of patency was lower in the fish oil (48%) than the placebo (62%). Fish oil thus may benefit some patients with an AV graft since time to thrombus was longer and thrombus rates were about half that of placebo.[64] Based on this evidence, the KDOQI guidelines are suggesting the use of fish oil supplements in patients with a newly created AV graft to reduce morbidity and the frequency of thrombosis. The guidelines state there is inadequate evidence to recommend fish oil supplementation in patients with an AV graft to prolong graft patency.

Fish oil supplements were also studied in patients scheduled to receive surgery for an AV fistula. Patients were randomized to receive either placebo (olive oil) or fish oil 4 g/day (EPA 46% and DHA 38%) starting the day prior to surgery for 12 weeks. The patients receiving aspirin 100 mg/day were similar in each study arm. The AV fistula failure rate during the first 12 months post-surgery was 47% in both groups with similar rates of thrombus formation in patients receiving fish oil vs placebo (22% vs 23%) including those receiving aspirin or placebo (20% vs 18%).[65] The KDOQI guidelines do not recommend the use of fish oil supplementation to prevent flow dysfunction in an AV fistula.[30]

Catheter-locking solutions have been associated with a reduction in catheter thrombosis. The instillation of unfractionated heparin (UFH), recombinant tissue plasminogen activator (rt-PA), or sodium citrate in each HD catheter lumen between HD sessions have demonstrated efficacy in reducing catheter thrombosis. Sodium citrate 4% is as effective as UFH but may offer a better safety profile at a reduced cost.[66] A systematic review and meta-analysis of randomized controlled trials of HD locking solutions containing UFH and citrate found significantly fewer bleeding episodes in the patients receiving citrate. The analysis found no difference between citrate and UFH for catheter patency.[67] Unfractionated heparin 5,000 units/mL twice weekly and recombinant tissue plasminogen activator (rt-PA) 1 mg/catheter lumen once weekly were instilled in patients receiving HD with a CVC. Alternating the catheter-locking solution regimen with rt-PA significantly decreased catheter malfunction compared to the patients receiving UFH only for catheter patency. The cost of catheter replacement and hospitalization may offset the cost of once weekly administration of rt-PA.

Based on their medical history, patients at high risk for catheter malfunction or bacteremia ($n = 373$) received post-HD catheter-locking solutions of rt-PA (1 mg/lumen) once weekly plus routine care with either sodium citrate 4% or UFH on the remaining post-HD sessions. Catheter malfunction significantly declined with weekly rt-PA treatment from 18.4 to 10.1 days/1,000 catheter days and the episodes of bacteremia declined from 0.28 to 0.25/1,000 catheter days. Most patients (96%) received routine care with sodium citrate 4%, which may account for the small decline in bacteremia episodes. Overall, the increased cost of weekly rt-PA was not offset by the decline in catheter malfunction or bacteremia.[68] Taurolidine-based catheter solutions were examined in patients with a tunneled catheter ($n = 177$). Patients were randomized to receive either taurolidine citrate with urokinase (Tauro/U) once weekly plus taurolidine citrate with heparin (Tauro/Hep) twice a week ($n = 84$) or Tauro/Hep ($n = 93$) three times a week. During the 6-month study, no patients in the Tauro/U group required catheter replacement compared with three patients in the Tauro/Hep group. The use of rt-PA to restore catheter patency occurred at a lower rate with Tauro/U ($n = 5$) compared to Taurolock/Hep ($n = 12$). This was a short-term study; therefore, it is difficult to extrapolate long-term benefits until further studies are completed.[69] A catheter locking solution of taurolidine (1.35%), citrate (3.5%), and heparin (1,000 units) is seeking FDA approval for the prevention of CRBSI in patients receiving HD.

A prospective cohort study in patients ($n = 451$) receiving HD with a tunneled or non-tunneled catheter and either sodium bicarbonate 7.5% or 8.4%, or 0.9% normal saline as a catheter locking solution. Patients receiving the sodium bicarbonate locking solution had a significantly lower rate of thrombosis and blood stream infections compared the 0.9% NaCl group ($P < 0.0001$).[70] UFH or citrate (concentrations less than 5%) are listed by KDOQI as catheter locking solution options. The KDOQI guidelines consider citrate and UFH to have similar efficacy for survival and maintaining patency. Catheter locking solutions to prevent infections with taurolidine, tinzaparin or gentamicin are not recommended by KDOQI based on the current evidence. In patients with an indwelling catheter at high risk for a catheter-related blood stream infection (CRBSI) defined as patients with multiple prior CRBSIs and/or a *S aureus* nasal carriers may benefit from prophylactic instillation of rt-PA once weekly.[30]

The therapeutic alternatives for the management of venous catheter thrombosis are listed in Table 64-6. If a catheter-related thrombus is suspected, a forced saline flush should be used to clear the catheter, followed by installation of a thrombolytic. A number of studies have been published using alteplase and reteplase and initial reperfusion rates for both were approximately 90%, respectively.[71] The efficacy, safety, and cost of alteplase, reteplase, and tenecteplase were compared, and venous catheter clearance rates were similar with reteplase (88% ± 4%) and alteplase (81% ± 37%), but markedly lower with tenecteplase (41% ± 5%).[71] The cost analysis favored the use of reteplase, however, to attain these savings, reteplase must be batch prepared. Reteplase is not FDA approved for this indication which may limit it use.[71] The instillation of a tissue plasminogen activator once weekly in a catheter may reduce catheter dysfunction and could be considered in select patients at a high risk of thrombosis.[30]

TABLE 64-6

Management of Hemodialysis Catheter Thrombosis

Nonpharmacologic therapy
Forced saline flush
Referral to vascular surgeon
Pharmacologic therapy
Alteplase: instill 2 mg/2 mL/catheter lumen port; attempt to aspirate after 30 minutes; may repeat dose if catheter function is not restored in 120 minutes; longer durations of instillation have been used.
Reteplase: instill 0.4 U/0.4 mL in each lumen, attempt to aspirate after 20-30 minutes, may repeat if necessary.

Alteplase is available commercially and is the only agent that is FDA approved, for venous catheter clearance, and is administered as a short dwell for 30 to 60 minutes, as a long dwell, or left in the catheter between treatments. No difference in patency rates between the short or long dwells has been demonstrated. Alteplase has also been given as a short infusion of 2 mg/h over 4 hours for a blocked catheter and 1 mg/h over 4 hours for sluggish blood flow. Infusions may theoretically be more efficacious than the dwell technique because the thrombus is only exposed to the thrombolytic at the tip of the catheter. Another consideration is dwell versus push techniques for thrombolytic therapy, with recent data indicating that a push protocol with alteplase is as effective and safe for managing HD catheter dysfunction and might be more practical than a dwell technique.[72]

A retrospective single-center study evaluated the dose of alteplase in patients receiving HD with a catheter requiring a thrombolytic for catheter dysfunction. Patients during the first 3 years of the study received alteplase 1 mg/lumen ($n = 108$) and during the last 3 years received alteplase 1 mg/lumen. Dwell time was 30 minutes and independent of dose. Patients receiving alteplase 2 mg dose had a lower rate of catheter removal due to dysfunction (10.2% vs 19.4%). Overall, the instillation of alteplase 2 mg compared to 1 mg resulted in a 89.2% success rate at resolving catheter occlusions versus 80.6% ($P = 0.036$).[73]

Infection

Patients who develop a fever during dialysis should immediately be evaluated for infection; blood cultures should be collected prior to the administration of any antibiotics. When an AV fistula infection is suspected, empiric broad-spectrum antimicrobial therapy must be initiated usually with vancomycin plus an aminoglycoside or extended spectrum beta-lactamase inhibitor. Antimicrobial therapy, if the infection is confirmed, should continue for a total of 6 weeks and should be tailored to culture sensitivities. Unfortunately, a suspected infection in an AV graft may require a surgical procedure to remove the infected graft material in addition to antimicrobial therapy. A suspected infection in a temporary catheter may warrant catheter removal and a culture of the catheter tip should be obtained.[31,74] Catheter-related infections are more common than infections of an AV fistula or graft; therefore, preventative care approaches are paramount. Preventative care includes minimizing the use and duration of catheters, proper disinfection and sterile technique, and the use of an antimicrobial ointment at the exit site (mupirocin 2%, povidone-iodine).[75] Dialysis unit protocols that employ universal precautions, limit the manipulation of the catheter, utilize an antiseptic wash (tincture of iodine, chlorhexidine, etc.) for skin preparation, and the use of facemasks by the patient and caregiver can significantly reduce the incidence of catheter-related bacteremia.[31,74,76] Topical application of 2% mupirocin ointment to a tunneled HD catheter exit site after each HD session can increase infection-free days. Current recommendations are to apply either povidone-iodine antiseptic ointment or polysporin triple ointment (bacitracin/gramicidin/polymyxin B) to the exit site after each HD session. Long-term monitoring of infection rates of patients receiving HD with a catheter did not reveal an increase in antibiotic resistance with a once-a-week application of a topical polysporin triple ointment to catheter exit sites.[77]

The Infectious Disease Society of America (IDSA) and KDOQI guidelines address catheter care and the diagnosis and management of catheter-related infections.[30,76] Peripheral blood draws, although recommended by IDSA, are often avoided in patients receiving HD to protect potential or future HD vascular access sites. Blood cultures are generally obtained from the blood tubing connecting the catheter to the HD machine. A prospective study examined blood cultures ($n = 178$) obtained from patients receiving HD suspected of a CRBSI. The blood cultures obtained from the HD circuit and venous catheter hub were the most sensitive, specific, and accurate for diagnosing CRBSI compared to blood cultures taken from a peripheral vein and either catheter hub or HD circuit.[78] A full-course of antimicrobial treatment is warranted if blood cultures are positive.[31,76] Empiric therapy with coverage for both gram-positive and gram-negative bacteria should be initiated after the blood cultures are obtained. The incidence of MRSA bacteremia warrants initial treatment for gram-positive coverage with vancomycin or daptomycin. If gram-negative antimicrobial coverage is warranted, an aminoglycoside or third-generation cephalosporin should be initiated depending on a center's protocols and antimicrobial susceptibilities.[31,76] Antimicrobial therapy de-escalation should occur once blood cultures identify an organism and antimicrobial susceptibility. For example, if the isolated organism is methicillin-sensitive *S. aureus*, administer IV cefazolin (20 mg/kg, rounded to the nearest 500 mg) after each dialysis session. Antibiotic selection should be based on bacterial coverage and the ability to optimize pharmacokinetics by administering a dose either during the last 30 to 60 minutes of HD treatment or during the rinse bath. This method minimizes additional dosages between HD sessions. Examples of antimicrobial agents that meet these objectives are vancomycin, cefazolin, ceftazidime, daptomycin, and aminoglycosides.[76,79]

The IDSA guidelines recommend removal of an infected catheter if *S. aureus*, *Pseudomonas* species, or *Candida* species are the infectious cause. Although removal of the catheter is warranted, this is not always possible in patients receiving HD because of limited vascular access options. Retaining an infected catheter significantly increases a patient's risk of bacteremia recurrence after completing a course of antibiotics; therefore, other options need to be considered. Options such as replacing the catheter over a guidewire or using a catheter-lock solution in conjunction with IV antibiotics are alternatives.[31,76]

The catheter salvage success rate when a catheter-lock solution is used in addition to systemic antibiotics is highly variable and pathogen dependent.[31,76] The IDSA guidelines recommend the use of catheter-lock solutions as adjunctive therapy after each dialysis session for 10 to 14 days in a patient whose catheter was not removed and bacteremia symptoms resolved in 2 to 3 days. The IDSA recommendations for antibiotic therapy are listed in Table 64-7.[76]

TABLE 64-7

Management of Hemodialysis Access Infection

1. Primary arteriovenous fistula
    A. Treat as subacute bacterial endocarditis for 6 weeks.
    B. Initial antibiotic choice should always cover gram-positive organisms (eg, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times/week or after each dialysis session).
    C. Gram-negative coverage is indicated for patients with diabetes, human immunodeficiency virus infection, prosthetic valves, or those receiving immunosuppressive agents, gentamicin 2 mg/kg IV with serum concentration monitoring.
2. Synthetic arteriovenous grafts
    A. Local infection—empiric antibiotic coverage for gram-positive, gram-negative, and *Enterococcus* (eg, gentamicin plus vancomycin then individualized after culture results available). Continue for 2–4 weeks.
    B. Extensive infection—antibiotics as above plus total resection.
    C. If access is less than 1-month-old, antibiotics as above plus remove the graft.
3. Tunneled cuffed catheters (internal jugular, subclavian)
    A. Infection localized to catheter exit site.
        i. No drainage—topical antibiotics (eg, mupirocin ointment).
        ii. Drainage present—gram-positive antibiotic coverage, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times/week.
    B. Bacteremia with or without systemic signs or symptoms.
        i. Gram-positive antibiotic coverage as in III.A.2.
        ii. If symptomatic at 36 hours, remove the catheter.
        iii. If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks.

Data from References 76,80.

Microbial colonization of a catheter could affect patency and a patient's access to dialytic treatment. An examination of the catheter-lock solutions, UFH 5,000 U/mL and tetra-sodium EDTA, found an increased rate of microbial colonization with UFH but the tetra-sodium EDTA solution had an increased rate of thrombosis.[81] Alternative solutions to UFH and tetra-sodium EDTA including catheter-lock solutions containing ethanol 30% combined with sodium citrate 4% or ethanol 70% with UFH 2,000 U/mL have been effective at decreasing CRBSI and improving catheter survival.[82]

Catheter-locking solutions have been utilized to prevent infection and thrombosis in HD catheters. A meta-analysis of randomized control trials of catheter-related bacteremia and antimicrobial lock solutions identified eight studies with 829 patients and more than 90,100 catheter days. Overall analysis found that the use of an antimicrobial locking solution significantly reduced the risk of a catheter-related infection (relative risk [RR] 0.32; 95% confidence interval [CI] 0.10-0.42).[83] A comparison of UFH 1,000 U/mL to the combination solution of 4% sodium citrate with gentamicin 320 μg/mL as a catheter-lock solution significantly reduced the incidence of catheter-related bloodstream infections.[84] The value of catheter-locking solutions for treatment and prevention of catheter-related infections is increasingly becoming evident, but the possibility of antibiotic resistance with the wide use of antibiotics in catheter locks remains a concern. Gentamicin resistance to coagulase-negative *Staphylococcus* was reported in a retrospective study using routine post-HD administration of gentamicin (4 mg/mL) combined with UFH (5,000 U/mL) as a catheter-lock solution. Over the 4-year study, there were 80 CRBIs with 21 episodes (26%) of gentamicin resistance identified. The increase in gentamicin resistance led to a discontinuation of the gentamicin-heparin catheter-lock solutions.[85]

PERITONEAL DIALYSIS

Although the concept of peritoneal lavage has been described as far back as the 1700s, it wasn't until the 1920s that PD was first employed as an acute treatment for uremia. It was used infrequently during subsequent years until the concept of PD as a chronic therapy for ESRD was proposed in the 1960s. Over the ensuing years, the number of patients receiving PD increased slowly until the early 1980s. At that time, several innovations in PD delivery systems were introduced, such as improved catheters and dialysate bags. These innovations led to improved outcomes, decreased morbidity, mortality, and a corresponding increase in the use of PD as a viable alternative to HD for the treatment of ESRD. However, the worldwide use of PD has declined over the past decade. Some patients, such as those with more hemodynamic instability (eg, hypotension) or significant residual renal function (RRF), and perhaps patients who desire to maintain a significant degree of self-care may be better suited to PD than to HD. Table 64-2 shows the advantages and disadvantages of PD.

Principles of Peritoneal Dialysis

⑤ The three basic components of HD—namely, a blood-filled compartment separated from a dialysate-filled compartment by a semipermeable membrane—are also present in PD.[4] In PD, the dialysate-filled compartment is the peritoneal cavity, into which dialysate is instilled via a peritoneal catheter that traverses the abdominal wall. The contiguous peritoneal membrane surrounds the peritoneal cavity. The cavity, which normally contains about 100 mL of lipid-rich lubricating fluid, can expand to a capacity of several liters. The peritoneal membrane that lines the cavity functions as the semipermeable membrane, across which diffusion and ultrafiltration occur. The peritoneal dialyzing membrane is comprised of a monocellular layer of peritoneal mesothelial cells, the basement membrane, and underlying connective and interstitial tissue. The peritoneal membrane has a total area that approximates body surface area (approximately 1-2 m^2). Blood vessels supplying and draining the abdominal viscera, musculature, and mesentery constitute the blood-filled compartment.

Unlike HD, the crucial components of PD cannot be manipulated to maximize solute and fluid removal. Because the blood is not in intimate contact with the dialysis membrane as it is in HD, metabolic waste products must travel a considerable distance to the dialysate-filled compartment. In addition, unlike HD, there is no easy method to regulate blood flow to the surface of the peritoneal membrane, nor is there a countercurrent flow of blood and dialysate to increase diffusion and ultrafiltration via changes in hydrostatic pressure. Similarly, there is no easy means available to manipulate the peritoneal membrane. Thus, to enhance PD clearance involve alterations in dialysate volume, dwell time, and the number of exchanges per day. For these reasons, PD is a less efficient process per unit time compared with HD, and must, therefore, be a virtually continuous procedure to achieve acceptable goals for clearance of metabolic waste products.

Peritoneal Dialysis Access

Access to the peritoneal cavity is via the placement of an indwelling catheter. Many types are available, and Fig. 64-3 shows an example.[4] Most catheters are manufactured from silicone rubber, which is soft, flexible, and biocompatible. A typical adult catheter is 40 to 45 cm long, 20 to 22 cm of which is inside the peritoneal cavity. Placement of the catheter is such that the distal end lies low in a pelvic gutter. The center section of the catheter has one or two cuffs made of a porous material that is tunneled inside the anterior abdominal wall so that the cuffs provide mechanical support and stability to the catheter, serve as a mechanical barrier to skin organisms, and prevent their migration along the catheter into the peritoneal cavity. The cuffs are placed at different sites surrounding the abdominal rectus muscle. The remainder of the central section of the catheter is tunneled subcutaneously before exiting the abdominal surface, usually a few centimeters below and to one side of the umbilicus.

FIGURE 64-3

The placement of the catheter exit site is one of the factors related to the development or prevention of exit-site infections and peritonitis. The external section of most peritoneal catheters ends with a Luer-Lok connector, which can be connected to a variety of administration sets. These catheters can be used immediately, if necessary, provided small initial volumes are instilled; however, a maturation period of 2 to 6 weeks is preferred.

Peritoneal Dialysis Procedures

⑥ Several variants of PD are clinically utilized in the United States. All variants of PD require the placement of a dialysis solution to dwell in the peritoneal cavity for some period, removing the spent dialysate, and then repeating the process. PD prescriptions can be delivered as continuous or intermittent and use manual or automated exchanges. Continuous PD involves intraperitoneal dialysate 24 hours/day, 7 days/week. A continuous ambulatory PD procedure uses manual exchanges, versus a continuous cycling PD procedure uses a cycler to perform the exchanges. Whereas an intermittent procedure involves the use of cycler to deliver PD for a portion of the day.[4] The prescribed dose of PD may be altered by changing the number of exchanges per day, by altering the volume of each exchange, or by altering the strength of dextrose or other osmotic agent in the dialysate for some or all exchanges. Increasing any one of these variables increases the effective osmotic gradient across the peritoneum, leading to increased ultrafiltration and diffusion (solute removal). If the dwell time is extended, equilibrium may be reached, after which time there will be no further water or solute removal. In fact, after a critical period, reverse water movement may occur.[4] In a basic CAPD system, the patient or caregiver is manually responsible for performing the prescribed number of dialysate exchanges. The patient is connected to a bag of prewarmed peritoneal dialysate via the PD catheter, by a length of tubing called a transfer set. The most common transfer set used is the Y transfer set which consists of a Y-shaped piece of tubing that is attached at its stem to the patient’s catheter, leaving the remaining two limbs of the Y attached to dialysate bags, one filled with fresh dialysate and the other empty. The spent dialysate from the previous dwell is drained into the empty bag, and the peritoneum is subsequently refilled from the bag containing fresh dialysate. The Y set is then disconnected and the bag containing the spent fluid and the empty bag that had contained fresh dialysate are detached and discarded. Typically, a patient instills 2 to 3 L of dialysate three times during the day with each exchange lasting 4 to 6 hours, and then a single dialysate exchange overnight lasting 8 to 12 hours. At the end of the prescribed dwell period, a new Y set is attached and the process is repeated. The process of outflow, aseptic manipulation of the administration set and catheter, and inflow requires a total time of approximately 30 minutes.

As described earlier, CAPD involves performing the dialysate exchanges manually, whereas automated systems collectively termed automated peritoneal dialysis (APD) performs the exchanges with a cycler. APD systems are designed for patients who are unable or unwilling to perform the necessary aseptic manipulations and for those who require more dialysis. The device is set up in the evening, and the patient attaches the peritoneal catheter to it at bedtime. The machine performs several short-dwell exchanges (usually 1–2 hours) during the night. This permits a long cycle-free daytime dwell of up to 12 to 14 hours. Typical APD regimens involve total 24-hour exchanges of approximately 12 L, which include one or more daytime instillations and dwell periods.[86] This type of regimen is referred to as APD with a “wet” day. The APD variant, nightly intermittent PD, has a similar theme, except that the peritoneal cavity tends to be dialysate-free during the day. This type of regimen is frequently referred to as APD with a “dry” day. A number of variants exist and depend largely on equipment availability, patient and prescriber preference, and whether the patient retains any RRF, which influences the quantity of dialysis prescribed.

The APD systems include continuous cycling PD (CCPD), tidal PD, and nocturnal intermittent PD. The prototypic form of APD is usually a hybrid between CAPD and continuous cycling PD, in which some of the daily exchanges (usually the overnight exchanges) are completed using an automated device. Other advances in PD procedures involve using continuous flow PD. This technique maintains a fixed intraperitoneal volume and rapid, continuous movement of dialysate into and out of the peritoneal cavity. To accomplish this, two PD catheters (an inlet and outlet catheter) and a means of generating a large volume of sterile dialysate are required. Dialysate is generated via conventional HD equipment or sorbent technology. In continuous flow PD, clearance of small solutes is three to eight times greater than with APD and approximates daily HD. Potential applications of continuous flow PD include daily home dialysis, treatment of acute kidney injury in the intensive care unit, and ultrafiltration of ascites.

Peritoneal Dialysis Solutions

All forms of PD use dialysate solutions, which are commercially available in volumes of 1 to 3 L in flexible polyvinyl chloride plastic bags. The most commonly used solutions that are commercially available contain an osmotic agent, electrolytes, and buffer. The solutions contain electrolytes, such as sodium (132-134 mEq/L [mmol/L]), chloride (96 mEq/L [mmol/L]), calcium (2.5-3.5 mEq/L [1.25-1.75 mmol/L]), and magnesium (0.5 mEq/L [0.25 mmol/L]). These solutions may contain dextrose (1.5%, 2.5%, 3.86%, or 4.25%) or icodextrin (a glucose polymer) at a concentration of 7.5%. The dextrose solutions are hyperosmolar (osmolarity range, 345-484 mOsm/L) and induce ultrafiltration (removal of free water) by crystalline osmosis. Dextrose is not the ideal osmotic agent for peritoneal dialysate because these solutions are not biocompatible with peritoneal mesothelial cells or with peritoneal leukocytes. The cytotoxic effects on these cells are mediated by the osmolar load and the low pH of the solutions, as well as the presence of glucose degradation products formed during heat sterilization of these products. Icodextrin PD solution contains icodextrin, a starch-derived glucose polymer. It has an osmolality of 282 to 286 mOsm/kg (mmol/kg), which is isoosmolar with serum. Icodextrin produces prolonged ultrafiltration by a mechanism resembling colloid osmosis resulting in ultrafiltration volumes similar to those with 4.25% dextrose. Icodextrin may have fewer of the metabolic effects associated with dextrose, such as hyperglycemia and weight gain. It is indicated for use during the long (8-16 hours) dwell of a single daily exchange in CAPD and APD patients. Lower glucose degradation product dialysate solutions are also available with similar solute concentrations, but with pH of 7.3.[4] These newer, biocompatible dialysate solutions are described as less harmful to the peritoneal membrane and preserve RRF to a greater extent than the available standard solutions.[4] Preservation of RRF in PD and HD patients is important as it decreases mortality and increases the time to the first episode of peritonitis. However, the putative benefits of the biocompatible dialysate solutions have not been completely borne out: their use has not consistently slowed the rate of decline in glomerular filtration rate as compared to standard solutions, although the incidence of peritonitis has been lower. Finally, the solutions contain buffers, lactate (0-40 mmol/L), and/or bicarbonate (0-34 mmol/L).

Adequacy of Peritoneal Dialysis

The most recent International Society of Peritoneal Dialysis practice guidelines argue that the assessment and prescription of PD should be a shared decision-making process between the patient and the care giving team. Ideally assessments should focus on (1) patient reported outcome measures (well-being, quality of life, symptomatology, etc.), (2) fluid status, (3) nutrition status, and (4) toxin removal (ie, solute clearance determination).[87] As in

HD, toxin removal can be quantified by the clearance of urea, by calculating *Kt/V*. The calculations determine a daily *Kt/V*, which is then converted into a weekly value that is relevant to PD patients.

PD adequacy is a major issue that has received considerable attention. The most recent KDOQI guidelines recommend that patients on PD have a total *Kt/V* of at least 1.7/week, including both PD *Kt/V and* residual kidney *Kt/V*.[86] It is important to note that RRF may provide a significant component of the total *Kt/V*. Patients may commence PD with a residual CLcr of approximately 9 to 12 mL/min (0.15-0.20 mL/s), which contributes a renal *Kt/V* of 0.2 to 0.4. Over a period of 1 to 2 years, if RRF progressively deteriorates, the total *Kt/V* will progressively diminish unless PD *Kt/V* is increased (by increasing the prescribed dose of PD) to compensate for the reduced renal *Kt/V*.

For patients producing less than 100 mL urine/day, the weekly *Kt/V* dose of 1.7 must be provided entirely by peritoneal clearance. For patients producing greater than 100 mL urine/day, combined renal and peritoneal urea clearances must exceed the weekly *Kt/V* dose of 1.7.[86] The weekly *Kt/V* dose should be measured within the first month of PD initiation and at least once every 4 months thereafter. It is imperative to detect subtle decreases in RRF along with poor adherence to make necessary alterations to the prescribed PD dose to attain adequate clearance of waste products.

The KDOQI guidelines also stress the importance of preserving RRF in PD patients because it is associated with decreased mortality. Typical measures to preserve RRF include preferential use of ACE-Is or ARBs, regardless of blood pressure, and avoidance of medications or procedures that are associated with insults to the kidney (eg, nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, aminoglycosides, intravenous iodinated radiocontrast dyes, withdrawal of immunosuppressant therapies from a transplanted kidney, hypovolemia, urinary tract obstruction, and hypercalcemia).[86]

Complications of Peritoneal Dialysis

Mechanical, medical, and infectious problems complicate PD therapy. Mechanical complications include kinking of the catheter and inflow and outflow obstruction; excessive catheter motion at the exit site, leading to induration and possible infection and aggravation of tissues; pain from impingement of the catheter tip on the viscera; or inflow pain resulting from a jet effect of too rapid dialysate inflow.

Table 64-8 lists the numerous medical complications of PD. An average PD patient absorbs up to 60% of the dextrose in each exchange. This continuous supply of calories leads to increased adipose tissue deposition, decreased appetite, malnutrition, and altered requirements for insulin in diabetic patients. Fibrin formation in dialysate is common and can lead to obstruction of catheter outflow. Infectious complications of PD are a major cause of morbidity and mortality and the transfer of patients from PD to HD therapies. A leading cause of infections are related to technique failure during PD exchanges. The two predominant infectious complications are peritonitis and catheter-related infections, which include both exit-site and tunnel infections.

TABLE 64-8

Medical Complications of Peritoneal Dialysis

Cause	Complication	Treatment
Glucose load	Exacerbation of diabetes mellitus	IP insulin
Fluid overload	Exacerbation of heart failure Edema Pulmonary congestion	Increase ultrafiltration Diuretics, if the patient has residual renal function
Electrolyte abnormalities	Hypercalcemia/Hypocalcemia	Alter dialysate calcium content
PD additives	Chemical peritonitis	Discontinue PD additives
Malnutrition	Albumin loss Loss of amino acids Muscle wasting Increased adipose tissue	Dietary changes Parenteral nutrition Discontinue PD
Unknown	Fibrin formation in dialysate	IP heparin

IP, intraperitoneal; PD, peritoneal dialysis.

Peritonitis

⑦ The incidence of peritonitis is influenced by connector technology, by the composition of patient populations, and by the use of APD versus CAPD. The Peritoneal Dialysis Outcomes and Practice Patterns Study (PDOPPS) is an international cohort study reporting on PD-related peritonitis and potential contributing factors such as exit-site prophylaxis. The rate of peritonitis was 0.26 (95% CI, 0.24-0.27) per patient-year in the United States with the causative organisms as gram-positive (37%), gram-negative (13%), culture-negative (16%), polymicrobial (5%), and yeast (1%). The most common exit site prophylaxis was topical aminoglycoside (72%) and topical mupirocin (13%).[88]

Peritonitis is a major cause of catheter loss in PD patients. The clinical presentation and diagnosis are listed in Table 64-9. A retrospective cohort study found a mortality rate of 0.07 per patient-year (95% CI, 0.06-0.08). The cause of mortality was identified as cardiovascular (56.3%) and infectious disease (17.6%). Patients who died from an infectious cause, 41.3% were related to peritonitis.[89] A statistically significant correlation between infectious complications and death rates has been reported: patients who had more than 1 peritonitis episode/year, 0.5 to 1 episode/year, or less than 0.5 episode/year, 50% died after 3, 4, and 5 years of therapy, respectively. It is important to note that these relationships are not necessarily cause and effect, as many of these patients succumb to cardiovascular events.[90]

TABLE 64-9

Clinical Presentation and Diagnosis of Peritoneal Dialysis-Related Peritonitis

General

- Patients generally present with abdominal pain and cloudy effluent

Symptoms

- The patient may complain of abdominal tenderness, abdominal pain, fever, nausea and vomiting, and chills

Signs

- Cloudy dialysate effluent may be observed
- Temperature may or may not be elevated

Laboratory Tests

- Dialysate white blood cell count >100/mm^3 (0.1×10^9/L), of which at least 50% are polymorphonuclear neutrophils
- Gram stain of a centrifuged dialysate specimen

Other Diagnostic Tests

- Culture and sensitivity of dialysate should be obtained

Peritonitis has several imprecise definitions, but guidelines suggest that an elevated dialysate white blood cell count of greater than 100/μL (0.1×10^9/L) with at least 50% polymorphonuclear neutrophils indicates the presence of inflammation, of which peritonitis is the most likely cause.[91] A patient who presents with abdominal pain and a cloudy effluent is usually given a provisional diagnosis of peritonitis. Inherent in this definition is a number of false-positive and false-negative diagnoses, because a small percentage of patients with culture-proven peritonitis will have clear dialysate, and some patients, such as menstruating females, may have cloudy PD effluent without clinical infection. Sterile culture peritonitis remains problematic; it is defined as an episode in which there is clinical suspicion of peritonitis, but for which the culture of the dialysate reveals no organism. There are several postulates for the high incidence (up to 20% of episodes) of culture-negative peritonitis. Many peritonitis-producing organisms are slime producers and may adhere to the peritoneal membrane or to the catheter surface and may be protected from exogenous antibiotics. Sufficient numbers of these bacteria may proliferate to cause peritoneal membrane inflammation and clinical peritonitis, but an inadequate number may seed into the peritoneal cavity to be recovered by conventional microbiologic techniques. In addition, free-floating planktonic bacteria may be rapidly phagocytosed by peritoneal white blood cells, thereby rendering them unavailable for culture.[92]

Contemporary methods have increased the recovery rate of organisms and decreased the culture-negative rate. Centrifugation is recommended as the optimum culture method. Centrifugation of a large volume of dialysate (50 mL), resuspension of the sediment in 3 to 5 mL of sterile saline, and subsequent inoculation in culture media produce a culture-negative rate less than 5%. If centrifuge equipment is not available, blood culture bottles can be directly injected with 5 to 10 mL of dialysate effluent. However, this method results in a culture-negative rate of up to 20%.[91]

The majority of infections are caused by gram-positive bacteria, of which *Staphylococcus epidermidis* is the predominant organism. There is no single predominant gram-negative organism. Together, gram-positive and gram-negative organisms account for 80% to 90% of all episodes of peritonitis and constitute the spectrum against which initial empiric therapy is directed.[93]

Catheter-Related Infections

A catheter-related infection in patients receiving PD includes both exit-site infection (ESI) and tunneled infection. Patients with previous infections tend to have a higher subsequent incidence. A case-controlled study found that 69.8% of patients receiving PD had at least one ESI over a 3-year period and are more likely to develop peritonitis (64%) compared to patients without an ESI.[94] The majority of ESIs are caused by *S. aureus*. In contrast to peritonitis, *S. epidermidis* accounts for less than 20% of ESIs. Although gram-negative organisms, such as *Pseudomonas*, are less common, they can result in significant morbidity. The diagnostic characteristics of these infections are somewhat vague but generally include the presence of purulent drainage, with or without erythema at the catheter exit-site. The risk of ESIs is increased several-fold in patients who are nasal carriers of *S. aureus*.[94]

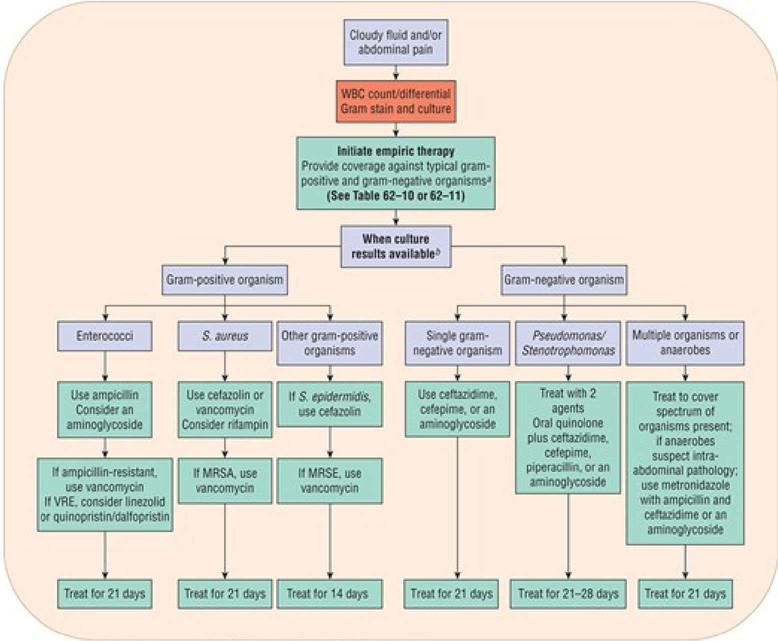
Management

Peritonitis

The International Society of Peritoneal Dialysis (ISPD) updated the Peritoneal Dialysis-Related Infections recommendations in 2016, which provide guidelines for treatments for peritonitis and tunneled and exit-site infections.[91] These PD-related infections are associated with dialysis modality treatment failures and substantial morbidity and mortality; therefore, appropriate pharmacotherapy treatment is essential. The ISPD guidelines specifically address the importance of peritonitis prevention, dialysis center antibiotic selection, and intraperitoneal (IP) antibiotic dosing and treatment duration for peritonitis.[91] In 2017, ISPD published catheter-related infection recommendations to prevent ESIs and described routine catheter care for PD patients.[93] Both guidelines provide a summary of best practices based on available evidence or consensus in areas where evidence exists. Figure 64-4 shows the pharmacotherapy recommendations for the treatment of bacterial peritonitis.

FIGURE 64-4

Pharmacotherapy recommendations for the treatment of bacterial peritonitis in peritoneal dialysis patients. [a]Choice of empiric treatment should be made based on the dialysis center's and the patient's history of infecting organisms and their sensitivities. [b]Final choice of therapy is guided by culture and sensitivity results. (MRSA, methicillin-resistant *Staphylococcus aureus;* MRSE, methicillin-resistant *Staphylococcus epidermidis; S. aureus, Staphylococcus aureus; S. epidermidis, Staphylococcus epidermidis;* VRE, vancomycin-resistant enterococci; WBC, white blood cell.)



Cloudy fluid and/or abdominal pain
WBC count/differential Gram stain and culture
Initiate empiric therapy Provide coverage against typical gram-positive and gram-negative organisms[a] (See Table 62–10 or 62–11)
When culture results available[b]
Gram-positive organism
Gram-negative organism
Enterococci
S. aureus
Other gram-positive organisms
Single gram-negative organism
Pseudomonas/ Stenotrophomonas
Multiple organisms or anaerobes
Use ampicillin Consider an aminoglycoside
Use cefazolin or vancomycin Consider rifampin
If S. epidermidis, use cefazolin
Use ceftazidime, cefepime, or an aminoglycoside
Treat with 2 agents Oral quinolone plus ceftazidime, cefepime, piperacillin, or an aminoglycoside
Treat to cover spectrum of organisms present; if anaerobes suspect intra-abdominal pathology; use metronidazole with ampicillin and ceftazidime or an aminoglycoside
If ampicillin-resistant, use vancomycin If VRE, consider linezolid or quinopristin/dalfopristin
If MRSA, use vancomycin
If MRSE, use vancomycin
Treat for 21 days
Treat for 21 days
Treat for 14 days
Treat for 21 days
Treat for 21–28 days
Treat for 21 days

The preferred delivery route for antibiotics is IP over IV therapy for the treatment of peritonitis. Antimicrobial dosing recommendations provided in the ISPD guidelines for CAPD dosing distinguish between intermittent (one exchange per day) and continuous therapy (all exchanges). The 2016 guidelines no longer provide APD IP drug dosing recommendations due to a "substantial knowledge gap" within this treatment area. The ISPD guidelines include oral and IV dosing recommendations that can be dosed either independent of or in conjunction with IP dosing.[91,93]

Following a single IP antibiotic dose, the drug concentrations achieved in dialysate and serum differ between intermittent and continuous methods. Intermittent IP therapy necessitates that a sufficient amount of drug transfers from the peritoneal cavity to the systemic circulation, thus allowing drug to diffuse back into the peritoneum during drug-free dialysate dwell time(s). Therefore, once daily dosing requires drug(s) be added to the exchange with the longest dwell time (at least 6 hours) to ensure maximum systemic exposure.

Continuous dosing recommendations may require a loading dose with the first IP dose and a maintenance dose for each subsequent exchange. Vancomycin, aminoglycosides, and cephalosporins generally are administered by either dosing method. It is recommended that a continuous dosing method be used for penicillins and fluoroquinolones. No matter which CAPD drug dosing method is used, the goal is to deliver and maintain adequate peritoneum drug concentrations. Intermittent or continuous dosing is effective for CAPD patients but IP dosing for APD patients may require a different dosing schedule. The rapid overnight dialysate exchanges with APD will increase solute clearance over a short time period. This is particularly important for first-generation cephalosporin agents. The ISPD guidelines recommend continuous dosing of a first-generation cephalosporin because of concerns over inadequate IP drug concentration during the shorter APD dialysate dwells. To maintain adequate peritoneum drug concentrations, patients may be advised to temporarily switch to CAPD delivery or manually instill dialysate with an antimicrobial agent during the day or the longest dwell. If a patient is not a good candidate for CAPD, the cycler can be reset to provide a longer dwell period or slower exchange rate to allow for drug transfer during APD.[91] Intermittent dosing of first-generation cephalosporin for APD does not sustain adequate drug concentrations for most organisms; therefore, continuous dosing may be more effective in providing better drug coverage. Oral ciprofloxacin attains adequate IP drug concentrations in patients receiving APD and is a therapeutic option if the pathogen is susceptible. Regarding RRF, in patients with substantial residual renal function, previous ISPD guidelines recommended dose adjustments for antibiotics with renal elimination. Recent studies suggest these dosing adjustments are not necessary to maintain adequate drug concentrations, resulting in ISPD removing the recommendation for dose adjustments from the 2016 guidelines. The ISPD dosing recommendations for IP antibiotics in CAPD and systemic therapy are shown in Tables 64-10 and 64-11, respectively.[91]

TABLE 64-10

Intraperitoneal Antibiotic Dosing Recommendations for Continuous Ambulatory Peritoneal Dialysis Patients

Drug	Intermittent (one exchange daily)	Continuous (all exchanges)
Aminoglycosides		
Amikacin	2 mg/kg	LD 25 mg/L; MD 12 mg/L
Gentamicin	0.6 mg/kg	LD 8 mg/L; MD 4 mg/L
Netilmicin	0.6 mg/kg	MD 10 mg/L
Tobramycin	0.6 mg/kg	LD 3 mg/kg; MD 0.3 mg/kg
Cephalosporins		
Cefazolin	15-20 mg/kg	LD 500 mg/L; MD 125 mg/L
Cefepime	1,000 mg	LD 250-500 mg/L; MD 100-125 mg/L
Cefoperazone	ND	LD 500 mg/L; MD 62.5-125 mg/L
Cefotaxime	500–1,000 mg	ND
Ceftazidime	1,000–1,500 mg	LD 500 mg/L; MD 125 mg/L
Ceftriaxone	1,000 mg	ND
Penicillins		
Amoxicillin	ND	MD 150 mg/L

Ampicillin	ND	MD 125 mg/L
Penicillin G	ND	LD 50,000 units/L; MD 25,000 units/L
Quinolones		
Ciprofloxacin	ND	MD 50 mg/L
Others		
Vancomycin	15-30 mg/kg Q5-7d[a]	LD 30 mg/kg; MD 1.5 mg/kg/bag
Daptomycin	ND	LD 100 mg/L; MD 20 mg/L
Aztreonam	2 g	LD 1,000 mg/L; MD 250 mg/L
Teicoplanin	15 mg/kg q 5 days	LD 400 mg/bag; MD 20 mg/bag
Linezolid	ND	Oral 200-300 mg daily
Clindamycin	ND	600 mg/bag
Polymixin B	ND	MD 300,000 Unit (30 mg)/bag
Meropenem	1 g	ND
Antifungals		
Fluconazole	200 mg IP every 24-48 hours	ND
Voriconzaole	2.5 mg/kg IP	ND
Combinations		
Ampicillin/sulbactam	2 g/1 g q 12 h	LD 750 mg/L/100 mg/L, MD 100 mg/L
Pipercillin/tazobactam	ND	LD 4 g/0.5 g; MD 1 g/0.125 g
Imipenem/cilastatin	500 mg in alternate exchanges	LD 250 mg/L, MD 50 mg/L
Quinupristin/dalfopristin[b]	25 mg/L in alternate exchanges[a]	ND

[a] Supplemental doses may be required for APD patients.

[b] Given in conjunction with 500 mg intravenous twice daily.

LD, loading dose in milligram; MD, maintenance dose in milligram; NA, not applicable; ND, no data.

TABLE 64-11

Systemic Antibiotic Dosing Recommendations for Treatment of Peritonitis

Drug	Dosing
Ciprofloxacin	Oral 250 mg twice daily
Levofloxacin	Oral 250 mg daily
Moxifloxacin	Oral 400 mg daily
Ertapenem	IV 500 mg daily
Linezolid	IV or oral 600 mg twice daily
Rifampicin	450 mg daily for body weight ≤50 kg, 600 mg daily for body weight ≥50 kg
Trimethoprim/Sulfamethoxazole	Oral 160 mg/800 mg twice daily
Amphotericin	IV test dose 1 mg; starting dose 0.1 mg/kg/day over 6 hours increase to target dose 0.75-1.0 mg/kg/day
Caspofungin	IV 70 mg load, then 50 mg daily
Fluconazole	Oral 200 mg loading, then 50 mg daily
Flucytosine	Oral 1 g daily
Posaconazole	IV 400 mg every 12 hours
Voriconazole	Oral 200 mg every 12 hours

Adapted from Li PK, Szeto CC, Piraino B, et al. ISPD peritonitis recommendations: 2016 update on prevention and treatment. Perit Dial Int. 2016;36:481–508.

Initial empiric therapy for peritonitis, regardless of whether a Gram stain was performed, or organisms were identified, should include agents effective against both gram-positive and gram-negative organisms. Antibiotic selection should be based on a dialysis center's antibiogram or resistance patterns, a history of the patient's infections, and the organism's antibiotic sensitivity profile. In many cases, a first-generation cephalosporin such as cefazolin in combination with a second drug that provides broader gram-negative coverage, such as ceftazidime, cefepime, or an aminoglycoside, will prove suitable. Patients with documented allergy to cephalosporin antibiotics can be treated with vancomycin and an aminoglycoside. High rates of methicillin resistance have been reported by many dialysis centers, and vancomycin should be used as first-line therapy against gram-positive organisms for patients treated at these centers. Monotherapy with agents providing both gram-positive and gram-negative coverage is an alternative option. Both imipenem-cilastin and cefepime are effective in treating CAPD-related peritonitis.[95]

After culture and sensitivity results are obtained, antibiotic therapy should be adjusted appropriately (see Fig. 64-4). Tables 64-10 and 64-11 list doses for antibiotics. Treatment should be continued for 14 to 21 days. If the patient does not show signs of clinical improvement within 72 hours after antibiotic treatment is initiated, the culture should be repeated, and the patient reevaluated. If the peritoneal dialysate white blood cell count remains high after 4 days of appropriate antibiotic therapy, clinicians should consider removing the peritoneal catheter, starting IV antibiotics, and initiating HD for dialytic maintenance therapy.

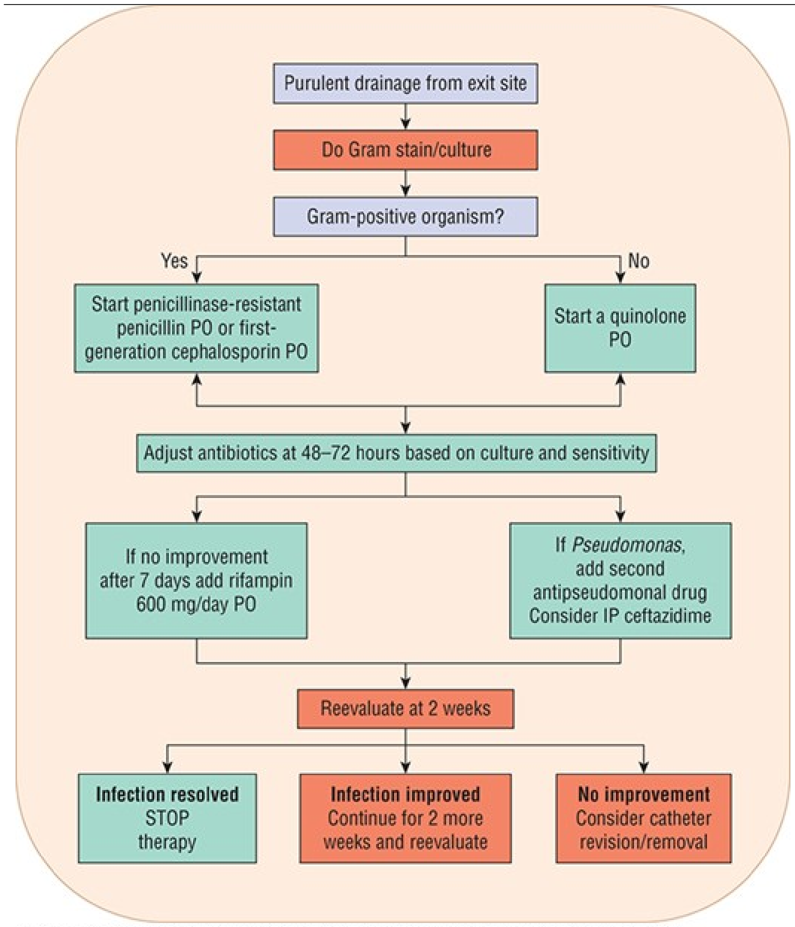
Fungal peritonitis is associated with a poor prognosis and high morbidity and mortality. One problem with prospective assessment of antifungal regimens is the infrequency with which these infections occur. This makes it difficult to design and implement comparative studies. Most literature about antifungal treatment is therefore retrospective or limited to reports of local experience. As a result, the ISPD recommendations for treatment of fungal peritonitis are somewhat vague and treatment should be based on culture and sensitivity results. However, one area that has been clarified is the question as to whether the PD catheter should be removed. The ISPD recommendations are to remove the catheter immediately after identifying fungi. If the Gram stain indicates the presence of yeast, treatment may be initiated with IV amphotericin B and oral flucytosine. Once culture and sensitivity results are available, fluconazole, caspofungin, or voriconazole may replace amphotericin B. Guidelines recommend amphotericin B be administered IV and not IP as this agent can cause chemical peritonitis and pain and has poor peritoneal bioavailability. Treatment with an oral agent continues for an additional 10 days after catheter removal. It remains unclear whether there is any benefit from fungal prophylaxis. Recommendations are also provided for the treatment of mycobacterial, or tuberculous, peritonitis. Although this infection is a rare complication, it can be difficult to diagnose, and treatment requires multiple drugs.[91]

Catheter-Site Infections

Topical antibiotics and disinfectants are effective agents for the prevention of ESIs. Gram-positive organisms should be treated with oral penicillinase-resistant penicillin or a first-generation cephalosporin such as cephalexin (Fig. 64-5). Rifampin may be added, if necessary, in slowly resolving or particularly severe *S. aureus* infections. Vancomycin should be avoided in routine or empiric treatment of gram-positive catheter-related infections but will be necessary for methicillin-resistant *S. aureus*. Treatment for gram-negative organisms consists of oral quinolones if the organism is susceptible. The effectiveness of oral quinolones may be diminished owing to chelation interactions with drugs containing divalent and trivalent ions, which are commonly taken by dialysis patients. Administration of quinolones should occur at least 2 hours prior to these drugs. In cases where *Pseudomonas aeruginosa* is the pathogen, a quinolone should not be used as monotherapy. Options for a second anti-pseudomonal drug include the IP administration of an aminoglycoside, ceftazidime, cefepime, piperacillin, imipenem-cilastatin, or meropenem. In all cases, antibiotics should be continued until the exit site is normal; 2 to 3 weeks of therapy may be necessary. A patient with a catheter-related infection that progresses to peritonitis will usually require catheter removal.[91,93]

FIGURE 64-5

Management strategy of exit-site infections for peritoneal dialysis patients. (IP, intraperitoneal; PO, orally) (*Data from Reference 93.*)



Purulent drainage from exit site
Do Gram stain/culture
Gram-positive organism?
Yes
No
Start penicillinase-resistant penicillin PO or first-generation cephalosporin PO
Start a quinolone PO
Adjust antibiotics at 48–72 hours based on culture and sensitivity
If no improvement after 7 days add rifampin 600 mg/day PO
If *Pseudomonas*, add second antipseudomonal drug Consider IP ceftazidime
Reevaluate at 2 weeks
Infection resolved STOP therapy
Infection improved Continue for 2 more weeks and reevaluate
No improvement Consider catheter revision/removal

Prevention of Peritonitis and Catheter Exit-Site Infections

⑧ Attempts to prevent peritonitis and catheter-related infections have included refinement of connector system technology (Luer-Lok connectors), enhanced patient training techniques, and the use of prophylactic antibiotic regimens and vaccines. Several antimicrobial agents have been examined as prophylaxis against peritonitis and tunnel-related infections. Rifampin 300 mg orally taken twice a day for 5 days, then repeated every 3 months, decreased the number of catheter-related infections, but not the incidence of peritonitis. The efficacy of other antibiotic prophylaxis for peritonitis and catheter-related infections is limited but long-term, extended-duration prophylaxis with penicillins or cephalosporins is not effective.[91,93]

Nasal carriage of *S. aureus* is associated with an increased risk of catheter-related infections and peritonitis.[91,93] In addition, diabetic patients and those on immunosuppressive therapy are at increased risk for *S. aureus* catheter infections. Prophylaxis with intranasal mupirocin (twice daily for 5-7 days every month), mupirocin (daily) at the exit site, or oral rifampin can effectively reduce *S. aureus* ESIs. Because of the minimal toxicity of mupirocin and the risk of rifampin resistance, mupirocin regimens are preferred.[91,93] However, it is important to note that *S. aureus* isolates with a high degree of resistance to mupirocin have been isolated from PD patients using prophylactic mupirocin at the peritoneal catheter exit-site. A recent study did not observe resistance patterns with the use of mupirocin. Patients in this study applied mupirocin to the exit site either once or thrice weekly. After 3 years, patients in the once-weekly group had an ESIs (0.26 episodes/patient/year) and peritonitis (0.36 episodes/patient/year) but patients in the thrice-weekly group had an ESIs (0.11 episodes/patient/year) and peritonitis (0.24 episodes/patient/year). The thrice weekly group had a significant reduction in ESIs ($P = 0.030$ and peritonitis ($P = 0.04$).[96] In addition, gentamicin cream applied daily to the exit site has been found to effectively reduce both *S. aureus* and *P. aeruginosa* ESI.[91,93] However, a comparison of mupirocin 2% and gentamicin 0.1% creams for exit-site prophylaxis noted a decrease in gentamicin susceptibility patterns for *Enterobacteriaceae* (12%) and *Pseudomonas* (14%).[97]

A retrospective study of topical chlorhexidine and mupirocin for the prevention of exit-site infections (ESI) in patients receiving PD. Patients received routine exit-site cleaning with 10% povidone-iodine followed by topical application to the exit site with mupirocin ($n = 162$) or chlorhexidine ($n = 175$). Patients receiving chlorhexidine had a higher rate of ESIs compared to mupirocin (0.22 vs 0.12 episodes/year) ($P = 0.048$). This study found no significant difference in time to first ESI ($P = 0.10$), rate of peritonitis ($P = 0.95$), or hospitalizations ($P = 0.21$).[98] A double-blinded, randomized controlled trial compared the use of the topical ointments mupirocin to polysporin triple (P^3; bacitracin, gramicidin and polymixin B) in PD patients ($n = 201$) for the prevention of PD-related infections. Patients applied the ointment to the exit site with each dressing change and were followed for up to 18 months. No significant difference was found between groups for time to first PD-related infections ($P = 0.41$) for either agent but a significant increase in fungal infections was observed in the P^3 versus mupirocin group (7 vs 0; $P = 0.01$). The authors concluded that the use of P^3 for PD-related infection prophylaxis was not superior to mupirocin and may increase the risk of fungal infections.[99]

The use of polyhexanide was compared to povidone–iodine to prevent ESIs in PD patients in a single-center prospective open label study ($n = 46$). After 12 months, there was a lower rate of overall infections ($P = 0.037$) and exit-site infections ($P = 0.032$) with use of polyhexanide compared to povidone-iodine. The infection source in the polyhexanide group was identified as *P. aeruginosa* ($n = 3$), but in the povidone–iodine group ($n = 9$) three sources were identified: *S. aureus* ($n = 6$), *Corynebacterium jeikeium* ($n = 2$), and *P. aeruginosa* ($n = 1$). During the study, no infected catheters required removal.[100]

CONCLUSION

Because of the limitation of available kidneys for transplantation, HD and PD remain the most widely available and commonly used ESRD treatments. Despite continual advances in dialysis and transplantation, kidney disease is associated with significant morbidity and mortality. Given the lack of a true cure for kidney disease, emphasis has been placed on the prevention and early detection of kidney disease. Goals set by the KDOQI, the Healthy People 2020 initiative, and the Centers for Medicare and Medicaid Services' CPM Project provide guidance and direction for all healthcare practitioners. In fact, there have been significant reductions in the incidence rate of ESRD, enhanced timing and selection of the preferred access placement, and mortality and morbidity.[101,102] For patients with ESRD, a focus on quality of life and rehabilitation is now a valuable and viable goal toward which the nephrology community should direct its research resources. Several links to patient-related videos that discuss CKD patient experiences are presented in Table 64-12. Although prevention of ESRD is the primary goal for clinicians and adequate access to renal transplantation is secondary, dialysis will likely be a part of the treatment paradigm for ESRD for many years to come.

SELF-ASSESSMENT QUESTIONS

1. The most commonly used treatment for end-stage renal disease is:

   A. Home hemodialysis

   B. Continuous ambulatory peritoneal dialysis

   C. In-center hemodialysis

   D. Renal transplantation

2. In comparison to hemodialysis, peritoneal dialysis is associated with:

   A. Higher clearances of both solutes and water

   B. The need for patients to come to the dialysis clinic three times/week

   C. A lower technique failure rate

   D. The potential for better preservation of residual renal function

3. Which of the following is the most important indication for initiation of chronic dialysis therapy?

A. Elevated blood urea nitrogen concentrations (greater than 60 mg/dL [21.4 mmol/L]).

B. Estimated glomerular filtration rate less than 25 mL/min/1.73 m^2.

C. Persistent symptoms associated with worsening renal function.

D. Hyperphosphatemia.

4. Which one of the following HD vascular access methods is considered to be the most desirable to use clinically and why?

A. Arteriovenous graft, because of the desire for long lasting placement

B. Arteriovenous fistula, because of lower rates of infection and thrombosis

C. Central venous catheter, because of easy placement

D. Venous catheter, because of the desire for long lasting placement

5. Which one of the following dialysis membranes is most likely to remove larger molecular weight drugs, such as vancomycin, during hemodialysis?

A. Conventional hemodialysis

B. High-efficiency hemodialysis

C. High-flux hemodialysis

D. Peritoneal membrane

6. Which one of the following statements is true regarding peritoneal dialysis?

A. In comparison to hemodialysis, peritoneal dialysis is more efficient at removing solutes and water.

B. During peritoneal dialysis, there is countercurrent flow of blood and dialysate, which increases diffusion and convection.

C. Blood flow to the peritoneal membrane can be regulated but to a greater degree than blood flow through a vascular access in hemodialysis.

D. The peritoneal membrane functions as the semipermeable membrane.

7. To provide adequate peritoneal dialysis:

A. Weekly *Kt*/*V* should exceed 1.7 for CAPD patients.

B. Daily *Kt*/*V* should exceed 1.7 for CAPD patients.

C. Residual renal function is not considered an important factor in the *Kt/V*.

D. *Kt/V* should be at least 2.0 for patients without residual renal function.

8. RC is a 63-year-old patient with ESRD receiving outpatient hemodialysis thrice weekly and has experienced several episodes of intradialytic hypotension. Which of the following should be considered to minimize RC's intradialytic hypotension?

A. Stretching exercises

B. Anti-hypertensive medications should be taken 2 to 3 hours prior to hemodialysis

C. Discourage food and beverage intake during dialysis

D. Increase the dialysate temperature

9. The preferred route for antibiotics to treat a patient with PD related peritonitis is:
   A. Intravenous administration with dosing based on an estimated GFR of less than 15 mL/min/1.73 m^2.
   B. Intravenous administration with the dose increased by 25% for patients with urine output greater than 100 mL/day.
   C. Intraperitoneal administration of an antibiotic in one PD exchange per day in patients receiving CAPD.
   D. Intraperitoneal administration of an antibiotic with the same dose for patient receiving either CAPD or APD.
10. Which of the following is true regarding PD catheter–related infections?
   A. Topical antibiotics and disinfectants are ineffective in preventing PD catheter-related infections.
   B. Vancomycin is the antibiotic of choice for gram-positive PD catheter-related infections.
   C. PD catheter-related infections that progress to peritonitis seldom need to have the catheter removed.
   D. Gram-positive organisms should be treated with an oral penicillinase-resistant penicillin or a first-generation cephalosporin such as cephalexin.
11. A 64-year-old male who receives regular hemodialysis for the past 3 years with an AV graft has diminished blood flow through his AV graft. Which one of the following would be best to restore AV graft blood flow for this patient?
   A. Alteplase
   B. Tenecteplase
   C. Heparin
   D. 4% sodium citrate
12. AV graft blood flow for this patient has been restored and the nephrologist is discussing adding an oral agent to prevent AV graft thrombosis in this patient. Which one of the following would be best to recommend for this patient now?
   A. Warfarin
   B. Aspirin
   C. Fish oil supplement
   D. No therapy
13. A 67-year-old female hemodialysis patient receiving regular hemodialysis for the past year has had several episodes of symptomatic intradialytic hypotension that was being treated with midodrine. The patient complained of tingling in her hands and feet and subsequently stopped taking midodrine. Which one of the following would be best to recommend for this patient now?
   A. Advise the patient to take midodrine as needed.
   B. Initiate paroxetine 10 mg once daily on non-hemodialysis days.
   C. Initiate intranasal desmopressin acetate one spray three times a week.
   D. Review vital readings and current medications for this patient.
14. A 71-year-old female peritoneal dialysis patient has been diagnosed with a catheter exit-site infection and empiric antibiotic therapy needs to be initiated. Which one of the following would be best to recommend for this patient now?

A. Vancomycin

B. Rifampin

C. Cephalexin

D. Ciprofloxacin

15. The prevention of hemodialysis catheter exit-site infections requires a multistep approach that includes a topical antibiotic applied to the exit-site and/or catheter tip. Which of the following agents may increase the risk of resistant *Enterobacteriaceae* infections in patients receiving peritoneal dialysis?

A. Mupirocin ointment

B. Gentamicin cream

C. Povidone-iodine solution

D. Polysporin triple ointment

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** In-center hemodialysis is the most common treatment for ESRD in the United States

2. **D.** Peritoneal dialysis is associated with greater potential for preservation of residual renal function than the other modalities listed

3. **C.** The decision to initate renal replacement therapy, should not only be based upon a decline in renal function below a cutoff, but based upon the development of symptoms associated with that decline in renal function and complications that arise because of it.

4. **B.** The native AV fistula has many advantages including providing the longest survival time of all blood-access devices and the lowest rate of complications such as infection and thrombosis.

5. **C.** High-flux membranes are now used in the vast majority of patients because they are capable of removing high-molecular-weight endogenous substances, such as β2-microglobulin, and medications such as vancomycin.

6. **D.** The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane.

7. **A.** The most recent KDOQI guidelines recommend that patients on PD have a total *Kt/V* of at least 1.7/week, including both PD *Kt/V and* residual kidney *Kt/V*.

8. **C.** Prevention of intradialytic hypotension (IDH) should be tried with nonpharmacologic approaches before pharmacologic agents are prescribed. The ingestion of food and beverage during a hemodialysis session could increase splanchnic blood flow and a redistribution of blood volume. This change in blood flow could decrease blood pressure and result in IDH.

9. **C.** Intraperitoneal administration is the preferred route for antibiotics to treat a patient with PD related peritonitis. The drug therapy is administered directly to the infected area dwells in the peritoneum for at least 6 hours to enhance its effectiveness.

10. **D.** Treatment of PD catheter-related infections require systemic antimicrobial therapy. The ISPD guidelines recommend initial treatment with an oral penicillinase–resistant penicillin or a first-generation cephalosporin such as cephalexin for infections caused by Gram-positive bacteria.

11. **A.** To restore blood flow for an AV graft, a thrombolytic would be the best choice. Alteplase is FDA approved for the treatment of clotted or sluggish hemodialysis vascular access. Heparin and sodium citrate are used to prevent thrombus formation.

12. **D.** The KDOQI 2019 guidelines for vascular access do not recommend oral antiplatelet or anticoagulant agents to diminish the occurrence of flow dysfunction in patients with an existing AV graft. The use of antiplatelet or anticoagulant agents to maintain vascular access patency showed little to no

benefit in several studies but there was an increased risk of bleeding.

13. **D.** Patients with intradialytic hypotension should have their vitals reviewed to determine when blood pressure changes occur during a HD session. A decrease in blood pressure could be due to aggressive fluid removal or dialysate that is too warm causing vasodilation. A patient's medications should be reviewed to determine if drug therapy is contributing to hypotension. A patient taking anti-hypertensive agents may need to adjust the timing of medications to after their HD session or avoid taking on HD days.

14. **C.** Treatment of PD catheter-related infections require systemic antimicrobial therapy. The ISPD guidelines recommend initial treatment with an oral penicillinase-resistant penicillin or a first-generation cephalosporin such as cephalexin for infections caused by gram-positive bacteria.

15. **B.** Gentamicin 0.1% creams is as effective for exit-site prophylaxis but there is concern that gentamicin susceptibility may be decreased. One study found a 12% decrease in gentamicin susceptibility for *Enterobacteriaceae* when gentamicin 0.1% cream was applied topically to a PD catheter.

Chapter 65: Drug-Induced Kidney Disease

Thomas D. Nolin; Mark A. Perazella

KEY CONCEPTS

KEY CONCEPTS

① The initial diagnosis of drug-induced kidney disease (DIKD) typically involves detection of elevated serum creatinine (S_{cr}) and blood urea nitrogen, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug.

② DIKD is best prevented by avoiding the use of potentially nephrotoxic agents for patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques, such as hydration, may be used to reduce potential nephrotoxicity.

③ Acute tubular injury/necrosis (ATN) is the most common presentation of DIKD in hospitalized patients. The primary agents implicated are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, and osmotically active agents.

④ Angiotensin-converting enzyme inhibitors (ACEIs), angiotensin-receptor blockers (ARBs), and nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with hemodynamically mediated kidney injury, the pathogenesis of which is a decrease in glomerular capillary hydrostatic pressure.

⑤ Acute allergic interstitial nephritis (AIN) is observed in up to 27% of kidney biopsies performed for hospitalized patients with unexplained acute kidney injury (AKI). Clinical manifestations of AIN typically (but not always) present approximately 14 days after initiation of therapy and may include fever, maculopapular rash, eosinophilia, arthralgia, as well as pyuria, hematuria, proteinuria, and oliguria.

This website is useful to enhance student understanding of risk factors for and commonly used drugs that are associated with nephrotoxicity. Watch the video titled, “Keeping Kidneys Safe: Know How Medicines Affect the Kidneys,” https://tinyurl.com/ybjao5qg. The video provides a brief overview of glomerular physiology and hemodynamically mediated nephrotoxic effects of nonsteroidal anti-inflammatory drugs and renin-angiotensin system blockers.

INTRODUCTION

Numerous diagnostic and therapeutic agents have been associated with the development of drug-induced kidney disease (DIKD) or nephrotoxicity. It is a relatively common complication with variable presentations depending on the drug and clinical setting, inpatient or outpatient. Manifestations of DIKD may include acid–base abnormalities, electrolyte imbalances, urine sediment abnormalities, proteinuria, pyuria, and/or hematuria.[1] However, the most common manifestation of nephrotoxicity is a decline in the glomerular filtration rate (GFR) and a corresponding rise in serum creatinine (S_{cr})

concentrations. Initial diagnosis of nephrotoxicity is often delayed because it typically is based on the detection of elevated S_{cr}, for which there is a temporal relationship between the kidney injury (evidenced by the rise in S_{cr}) and exposure to the potentially nephrotoxic drug. This is consistent with contemporary definitions of acute kidney injury (AKI), which rely on either an abrupt increase in S_{cr} or an abrupt decline in urine output (see Chapter e60, "Evaluation of Kidney Function" and Chapter 61, "Acute Kidney Injury").[2]

Nephrotoxicity is often reversible if one discontinues the use of the offending agent, but in some cases it may evolve into AKI and may even progress to stage 5 chronic kidney disease (CKD) and end-stage kidney disease (ESKD). Many different mechanisms are responsible for the pathogenesis of DIKD, and the introduction of new drugs with novel mechanisms of action provides the potential for the identification of new presentations of AKI and CKD. This chapter reviews the epidemiology, pathophysiology, risk factors, and basic principles of prevention of DIKD. Detailed discussions of these issues plus management strategies are presented for the most commonly used agents that have been associated with a moderate-to-high likelihood of DIKD.

EPIDEMIOLOGY

The incidence and characteristics of outpatient or community-acquired DIKD are not well understood since mild toxicity is often unrecognized in this setting. The incidence of community-based AKI requiring dialysis is as high as 29.5 per 100,000 person years and 522.4 per 100,000 person years for patients not requiring dialysis.[3] Although the incidence of drug-induced AKI was not specifically reported, up to 20% of hospital admissions due to AKI have been attributed to nephrotoxicity acquired in the community setting.[4] The incidence of AKI is even higher in hospitalized patients and increases over time.[3,5] As many as 22% of adults and 34% of children worldwide experience AKI during a hospital admission.[6] While up to 30% of critically ill patients experience AKI during their hospitalization, one in four cases is associated with nephrotoxic medication exposure.[7] Indeed, drugs have been implicated in 26% of all cases of in-hospital AKI and as such are a recognized source of significant morbidity and mortality.[1]

① Because the most common manifestation of DIKD is a decline in GFR leading to a rise in S_{cr} and blood urea nitrogen (BUN), the onset of toxicity in hospitalized, acutely ill patients is most often recognized by routine laboratory monitoring. Decreased urine output may also be an early sign of toxicity, particularly with radiographic contrast media, nonsteroidal anti-inflammatory drugs (NSAIDs), and angiotensin-converting enzyme inhibitors (ACEIs). Other laboratory abnormalities such as electrolyte and acid-base disturbances often follow an increase in S_{cr}. In the outpatient setting, nephrotoxicity is often recognized by the development of symptoms such as malaise, anorexia, vomiting, volume overload (shortness of breath or edema), and hypertension. S_{cr} or BUN concentrations and urine collection for creatinine clearance may subsequently be measured to quantify the degree of decline in GFR. Marked intrasubject between-day variability of S_{cr} values has been noted (±20% for values within the normal range; see Chapter e60). Furthermore, they may be altered as the result of dietary changes and initiation of drug therapy, which may interfere with the assay procedure. Nevertheless, changes in S_{cr} or urine output consistent with the diagnostic criteria for AKI (see Chapter e60), when correlated temporally with the initiation of drug therapy, are a common threshold for the identification of DIKD.[1]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Drug-Induced Kidney Disease

General

- The most common manifestation is a decline in GFR leading to a rise in S_{cr} and BUN.
- Alterations in renal tubular function without loss of glomerular filtration may be evident.

Symptoms

- Patients may complain of malaise, anorexia, nausea, vomiting, shortness of breath, or edema, particularly in the outpatient setting.

Signs

- Decreased urine output may be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs, with progression to volume overload and hypertension.
- Proximal tubular injury: Metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium due to increased urinary losses.
- Distal tubular injury: Polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.

Laboratory Tests

- An abrupt (within 48 hours) reduction in kidney function defined as an absolute increase in S_{cr} of greater than or equal to 0.3 mg/dL (27 μmol/L), a percentage increase in S_{cr} of greater than or equal to 50% (1.5-fold from baseline) within 7 days, or a reduction in urine output (documented oliguria of less than 0.5 mL/kg/hr for more than 6 hours), when correlated temporally with the initiation of drug therapy may indicate drug-induced AKI.[1]
- Electrolyte (hyponatremia, hyperkalemia, hypo/hyperphosphatemia) and acid-base disturbances (metabolic acidosis) may also develop.

Other Diagnostic Tests

- Urinary excretion of *N*-acetyl-*β*-glucosaminidase, *γ*-glutamyl transpeptidase, glutathione *S*-transferase, and interleukin-18 are markers of proximal tubular injury and have been used for the early detection of AKI in critically ill patients.
- Kidney injury molecule-1 (KIM-1) is expressed in the proximal tubule and is upregulated for patients with ischemic acute tubular necrosis (ATN), appearing in the urine within 12 hours after the ischemic insult.
- Neutrophil gelatinase–associated lipocalin (NGAL) protein may be detected in the urine within 3 hours of ischemic injury.
- The urinary cell-cycle arrest biomarkers insulin-like growth factor–binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinase 2 (TIMP-2) can predict AKI in high-risk surgical patients, and clinical outcomes (death and the need for dialysis) in critically ill adults. These biomarkers may have an emerging role in detecting and/or minimizing DIKD.

Nephrotoxicity may also be evidenced by primary alterations in renal tubular function without a corresponding loss of glomerular filtration. In this setting, urinary enzymes and low-molecular-weight proteins may be used as earlier and more specific biomarkers of nephrotoxicity compared with S_{cr} and BUN, which are relatively insensitive markers of kidney injury.[8,9] S_{cr} and BUN are used as surrogates of kidney function, not injury per se, and typically significant kidney injury must have occurred days before a rise in either is evident. The emergence of novel biomarkers of kidney injury represents an important opportunity for earlier detection of DIKD. Urinary excretion of KIM-1, *N*-acetyl-β-glucosaminidase, γ-glutamyl transpeptidase, glutathione *S*-transferase, NGAL, and interleukin-18 (markers of proximal tubular injury) have been used for the early detection of acute kidney damage in several patient populations.[8–10] For example, the transmembrane protein KIM-1 is upregulated for patients with ischemic ATN, appearing in the urine within 12 hours after the ischemic insult. Urinary *N*-acetylglucosamine concentrations are a highly sensitive indicator of AKI and can detect AKI in critically ill patients up to 4 days prior to a rise in S_{cr}. Similarly, urinary NGAL is an early marker of AKI, preceding a rise observed in S_{cr} by up to 3 days.[11]

The urinary cell-cycle arrest biomarkers IGFBP7 and TIMP-2 predict AKI in high-risk surgical patients,[12] and clinical outcomes (death and the need for dialysis) in critically ill adults.[13] The clinical utility of IGFBP7 and TIMP-2 in detecting and/or minimizing DIKD remain unclear, but several preclinical studies suggest a potential clinical role and utility of monitoring TIMP or IGFBP for this purpose. For example, TIMP-1 is an effective biomarker of cisplatin-induced nephrotoxicity in human kidney cells,[14] and is useful in predicting aristolochic acid–induced kidney injury in rats.[15] The urinary biomarkers may facilitate the earlier detection of kidney injury and diagnosis of nephrotoxicity and minimize the long-term consequences of this common drug-induced disorder.

PRINCIPLES FOR PREVENTION OF DRUG-INDUCED NEPHROPATHY

② The primary principle for prevention of DIKD is to avoid the use of nephrotoxic agents for patients at increased risk for toxicity. Therefore, an awareness of potentially nephrotoxic drugs and knowledge of risk factors that increase kidney vulnerability are essential.[16] Exposure to these drugs often cannot be avoided; so, several interventions have been proposed to reduce the potential for the development of nephrotoxicity, for example, adjustment of medication dosage regimens based on accurate estimates of kidney function, and careful and adequate hydration to establish high urine flow rates.[17] Other preventative strategies are still theoretical and/or investigational and relate directly to the specific nephrotoxic mechanisms of a given drug.

The several specific drug-induced kidney structural-functional alterations that are responsible for the vast majority of cases of DIKD are listed in Table 65-1. This chapter discusses the pathophysiologic mechanisms responsible for the development of DIKD with these agents in detail, along with clinical presentation, prevention strategies, therapeutic management approaches, and relevant monitoring plans.

TABLE 65-1

Drug-Induced Kidney Structural-Functional Alterations

Tubular epithelial cell damage	
Acute tubular injury/necrosis • Aminoglycoside antibiotics • Radiographic contrast media • Cisplatin, carboplatin • Ifosfamide • Amphotericin B • Cyclosporine, tacrolimus • Adefovir, cidofovir, tenofovir • Pentamidine • Foscarnet • Zoledronate • Chimeric antigen receptor T-cells	Osmotic nephropathy • Mannitol • Dextran • IV immunoglobulin (sucrose) • Hydroxyethyl starch • SGLT-2 inhibitors
Hemodynamically mediated kidney injury	
• Angiotensin-converting enzyme inhibitors • Angiotensin II receptor blockers • SGLT-2 inhibitors	• NSAIDs • Cyclosporine, tacrolimus • OKT3

• Chimeric antigen receptor T-cells	• High dose interleukin-2
Obstructive nephropathy	
Crystal nephropathy • Acyclovir • Sulfonamides • Indinavir, atazanavir • Foscarnet • Methotrexate • Ascorbic acid, ethylene glycol, orlistat • Ciprofloxacin	Nephrolithiasis • Sulfonamides • Triamterene • Indinavir, atazanavir Nephrocalcinosis • Oral sodium phosphate solution
Glomerular disease	
Minimal change disease • NSAIDs, COX-2 inhibitors • Lithium • Pamidronate • Interferon-α and β Membranous disease • NSAIDs • Penicillamine • Captopril	Focal segmental glomerulosclerosis • Pamidronate • Interferon-α and β • Lithium • Sirolimus • Anabolic steroids • Tyrosine kinase inhibitors
Tubulointerstitial disease	
Acute allergic interstitial nephritis • β-Lactams • Ciprofloxacin • NSAIDs, cyclooxygenase-2 inhibitors • Proton pump inhibitors • Loop diuretics • Immune checkpoint inhibitors	Chronic interstitial nephritis • Cyclosporine • Lithium • Aristolochic acid • Combination analgesics Papillary necrosis • NSAIDs, combined phenacetin, aspirin, and caffeine analgesics
Renal vasculitis, thrombotic microangiopathy, and cholesterol emboli	
Vasculitis • Hydralazine • Propylthiouracil • Allopurinol • Penicillamine • Adalimumab • Minocycline • Sulfasalazine	Thrombotic microangiopathy • Cyclosporine, tacrolimus • Gemcitabine • Bevacizumab • Mitomycin C • Quinine Cholesterol emboli • Warfarin • Thrombolytic agents

COX-2, cyclooxygenase-2; SGLT-2, sodium-glucose co-transporter 2

TUBULAR EPITHELIAL CELL DAMAGE

③ Drugs that lead to renal tubular epithelial cell (RTEC) damage typically do so via direct cellular toxicity or ischemia. Damage is most often localized in the proximal and distal tubular epithelia and is termed “ATN” when cellular degeneration and sloughing from proximal and distal tubular basement membranes are observed. This classically manifests as cellular debris-filled, RTECs and RTEC casts and/or muddy brown granular casts in the urinary sediment.[18] Specific indicators of proximal tubular injury include metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium as a result of increased urinary losses.[19] Indicators of distal tubular injury include polyuria from failure to maximally concentrate urine (ie, nephrogenic diabetes insipidus), metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.[20]

Acute Tubular Injury/Necrosis

Acute tubular injury/necrosis (ATN) is the most common presentation of DIKD in the inpatient setting. The primary agents associated with this type of injury are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically active agents such as immunoglobulins, dextrans, hydroxyethyl starch, and mannitol.[21]

Aminoglycoside Nephrotoxicity

Incidence

Aminoglycoside antibiotic–associated nephrotoxicity may occur in between 10% and 25% of patients receiving a therapeutic course.[22,23] Critically ill patients appear to have a higher risk for nephrotoxicity with rates as high as 58%.[24] The large variance is in part a result of the use of different definitions of toxicity, variability between agents in the class, and the risk factors present in the study population.

Clinical Presentation

Clinical evidence of aminoglycoside-associated nephrotoxicity is typically seen within 5 to 7 days after initiation of therapy and manifests as a gradual progressive rise in S_{cr} and BUN and decrease in creatinine clearance.[23] Patients usually present with non-oliguria, that is, they maintain urine volumes greater than 500 mL/day and sometimes have microscopic hematuria and proteinuria.[21] Although renal magnesium wasting can occur (ie, daily excretion of more than 10-30 mg), the risk of symptomatic hypomagnesemia is generally low. Full recovery of kidney function is common if aminoglycoside therapy is discontinued immediately upon discovering signs of toxicity. However, severe AKI may develop occasionally, and for these individuals renal replacement therapy may be required (see Chapter 61). The diagnosis of aminoglycoside-associated nephrotoxicity is often difficult, particularly in critically ill patients with multiple comorbidities and is confounded by other factors that are independently associated with the development of AKI.[24] For instance, concurrent dehydration, sepsis, hypotension, ischemia, and use of other nephrotoxic drugs frequently contribute to AKI in patients who are receiving aminoglycosides.

Pathogenesis

Aminoglycoside-associated ATN is primarily due to accumulation of high drug concentrations within proximal tubular epithelial cells, and subsequent generation of reactive oxygen species that produce mitochondrial injury, which leads to cellular apoptosis and necrosis.[22] This results in cell sloughing from proximal tubular basement membranes into the tubular lumen, which can result in tubular obstruction and back leakage of the glomerular filtrate across the damaged tubular epithelium. Toxicity is related to cationic charge of the drugs in this class, which facilitates their binding to negatively charged renal tubular epithelial membrane phospholipids in the proximal tubules, followed by intracellular transport and concentration in lysosomes. The number of cationic groups on the drug molecule correlates with the degree of nephrotoxicity, which is consistent with the observation of higher rates of toxicity with neomycin versus gentamicin, followed by tobramycin, then amikacin.[23]

Risk Factors

Multiple risk factors for aminoglycoside-associated nephrotoxicity have been identified: the aggressiveness of aminoglycoside dosing, synergistic toxicity as the result of combination drug therapy, and preexisting clinical conditions of the patient (Table 65-2).[22,24]

TABLE 65-2

Potential Risk Factors for Aminoglycoside-Associated Nephrotoxicity

(A) Related to aminoglycoside dosing: Large total cumulative dose Prolonged therapy Trough concentration exceeding 2 mg/L[a] Recent previous aminoglycoside therapy
(B) Related to synergistic nephrotoxicity—Aminoglycosides in combination with: Cyclosporine Amphotericin B Vancomycin Diuretics Iodinated radiographic contrast agents Cisplatin NSAIDs
(C) Related to predisposing conditions in the patient: Preexisting kidney disease Diabetes mellitus Increased age Poor nutrition Shock Gram-negative bacteremia Liver disease Hypoalbuminemia Obstructive jaundice Dehydration Hypotension Potassium or magnesium deficiencies

[a] The equivalent concentration in SI molar units is 4.3 μmol/L for tobramycin and 4.2 μmol/L for gentamicin.

Prevention

Aminoglycoside-associated ATN may be prevented by careful and cautious selection of patients and the use of alternative antibiotics whenever possible and as soon as microbial sensitivities are known. Commonly used alternatives include fluoroquinolones (eg, ciprofloxacin or levofloxacin) and third- or fourth-generation cephalosporins (eg, ceftazidime or cefepime). When aminoglycosides are necessary, gentamicin, tobramycin, and amikacin are most commonly used, but therapy should be selected to optimize antimicrobial efficacy. Furthermore, it is imperative to avoid volume depletion, limit the total aminoglycoside dose administered, and avoid concomitant therapy with other nephrotoxic drugs.[22] Future therapeutic alternatives may include new aminoglycoside congeners that retain the desired bactericidal activity and yet are devoid of nephrotoxicity, and may also include concurrent use of antioxidant compounds such as alpha-lipoic acid, vitamin E, and *N*-acetylcysteine.[25,26]

Prospective, individualized pharmacokinetic monitoring has been associated with a decrease in the incidence of aminoglycoside-associated nephrotoxicity.[27] High-dose intermittent administration of aminoglycosides, termed once daily dosing, used in combination with other antibiotics, has been intensively investigated as a practical cost-effective method to maintain antimicrobial efficacy while reducing the risk of AKI.[27,28] The reduction in incidence may be the result of limited proximal tubular aminoglycoside uptake during the transient, high-peak serum concentrations, and because of the presence of low aminoglycoside concentrations for a greater proportion of the dosing interval, which facilitates excretion of the aminoglycoside.[22] Although greater clinical efficacy and reduced nephrotoxicity may be realized with once daily compared with standard dosing, seriously ill, immunocompromised, and elderly patients, as well as those with preexisting kidney disease, are not ideal candidates for this approach.

Management

Aminoglycoside use should be discontinued or the dosage regimen revised if AKI is evident (ie, there is an S_{cr} increase of 0.5 mg/dL [44 μmol/L] or more that is not attributable to another cause). Other nephrotoxic drugs should be discontinued if possible, and the patient should be maintained adequately hydrated and hemodynamically stable.[28] Short-term renal replacement therapy may be necessary, but ESKD is rarely the result of aminoglycoside toxicity alone.

Radiographic Contrast Media Nephrotoxicity

Incidence

Radiographic contrast media–induced AKI (CI-AKI) is the third leading cause of hospital-acquired AKI, accounting for 10% to 13% of cases.[29] Estimates of the incidence varies widely depending on the population studied and presence of risk factors; rising from less than 2% for patients with normal kidney function, to 17% in patients with impaired kidney function, and 23% to 50% of critically ill patients.[21,30,31] However, the incidence of AKI in patients receiving radiocontrast is commonly overestimated, with the true incidence approximately 5.5%.[32] CI-AKI is extremely rare with intravenous contrast administration in patients with an eGFR >30 mL/min/1.73 m^2.[33] As the number of risk factors associated with CI-AKI increases, there is a corresponding increase in the incidence of nephrotoxicity and mortality rates. Approximately fivefold increased risk of death is seen in patients who develop CI-AKI compared with those who do not, with the highest mortality rates observed for patients who developed AKI and required renal replacement therapy. Specifically, in-hospital mortality for patients who developed CI-AKI was 34% versus only 7% of patients who received contrast but did not develop AKI.[29] Moreover, a two-year mortality rate of 81% has been observed for patients who developed CI-AKI and required dialysis.[29]

Clinical Presentation

CI-AKI is usually transient in nature, presenting most commonly as nonoliguria with kidney injury apparent within the first 24 to 48 hours after the administration of contrast. The S_{cr} concentration usually peaks between 3 and 4 days after exposure, with recovery after 7 to 10 days.[23] However, irreversible oliguric (urine volume less than 500 mL/day) AKI requiring dialysis is seenin high-risk patients.[34] Urinalysis typically reveals tubular enzymuria with hyaline and granular casts but may also be completely void of casts. The urine sodium concentration and fractional excretion of sodium are frequently low, with the latter typically less than 1% (0.01).

Pathogenesis

The primary mechanisms by which contrast media induces nephrotoxicity are renal ischemia and direct cellular toxicity.[35] Renal ischemia likely results from systemic hypotension and simultaneous acute vasoconstriction caused by disruption of normal prostaglandin synthesis and the release of adenosine, endothelin, and other renal vasoconstrictors. Subsequently, a sustained reduction in renal blood flow of up to 25% that lasts for several hours immediately following contrast administration may be evident.[35] This reduced renal blood flow leads to a 50% reduction in oxygen partial pressure and renal ischemia, along with increased concentrations of contrast in the renal tubules, which exacerbates the direct cytotoxicity.[35,36] The extent of cellular toxicity is directly related to the duration of tubular cell exposure to contrast. Thus, preservation of high urinary flow rates with adequate hydration before, during, and after contrast administration is vital to keep renal blood flow as high as reasonably possible to minimize tubular cell exposure to the contrast agent.[36] In humans, plasma osmolality is normally between 275 and 290 mOsm/kg (mmol/kg). Since low- and high-osmolar contrast agents are hyperosmolar to plasma (ie, 600-800 mOsm/kg [mmol/kg] and ~2,000 mOsm/kg [mmol/kg], respectively), their use may result in osmotic diuresis, dehydration, renal ischemia, and increased blood viscosity caused by red blood cell aggregation.[37] Oxidative stress has also been implicated in the development of ATN after contrast administration, which may explain the possible benefit of the antioxidants *N*-acetylcysteine and ascorbic acid.[38]

Risk Factors

Decreased renal blood flow exacerbates the ischemic and direct cytotoxic effects of contrast media on the renal tubules. Therefore, preexisting kidney disease, particularly in those with estimated GFR less than 60 mL/min/1.73 m^2, is the most important risk factor, since lower GFR is associated with increasing levels of risk.[31] Other patient-specific risk factors include conditions associated with decreased renal blood flow (ie, congestive heart failure, dehydration/volume depletion, and hypotension), and patients with atherosclerosis and reduced effective circulating arterial blood volume appear to also have an elevated risk.[39,40] Diabetes is also a significant risk factor, likely due to coexisting kidney disease (diabetic nephropathy). The presence of multiple myeloma has traditionally been considered a relative contraindication for contrast use, but the risk is associated with concomitant dehydration, kidney disease, or hypercalcemia rather than the diagnosis itself. Larger volumes or doses of contrast and the use of low- as well as high-osmolar contrast agents are also independent predictors of CI-AKI.[39,40] Intra-arterial administration of contrast confers greater risk than IV administration.[31] Lastly, concurrent use of nephrotoxins and drugs that alter renal hemodynamics such as NSAIDs and ACEIs also increases risk. Risk factors are additive, and there is a proportional increase in the incidence of CI-AKI and associated mortality as the number of risk factors increases.[40]

Prevention

CI-AKI can be anticipated in the majority of patients who are at risk; so the use of preventative procedures is justified for virtually all patients. Table 65-3 lists the recommended interventions for prevention of contrast nephrotoxicity. All patients scheduled to receive contrast media should be assessed for risk factors, and the risk-to-benefit ratio should be considered.[29,39,40] High-risk patients can be identified by evaluating medical history and indication for the contrast procedure, along with their most recent S_{cr} concentrations. Nephrotoxicity is best prevented in high-risk patients by using alternative imaging procedures (eg, ultrasound, noncontrast magnetic resonance imaging, and nuclear medicine scans). However, if contrast media must be used, the smallest adequate volume should be administered.[29] If the ratio of the volume of contrast to be infused relative to the patient's creatinine clearance is greater than or equal to 3.7 (222 if creatinine clearance is expressed in units of mL/s), the likelihood of nephrotoxicity is markedly increased.[40] Therefore, in general, the volume of contrast administered should not be greater than twice the baseline estimated creatinine clearance.

TABLE 65-3

Recommended Interventions for Prevention of Contrast Media-Induced AKI[38–41]

Intervention	Recommendation	Recommendation Grade[a]
Contrast	• Minimize contrast volume/dose • Use noniodinated contrast • Use low- or iso-osmolar contrast agents	A-1 A-2 A-2
Medications	• Avoid concurrent use of potentially nephrotoxic drugs (eg, NSAIDs, aminoglycosides)	A-2
Isotonic sodium chloride (0.9%)	• Initiate infusion 3-12 hours prior to contrast exposure and continue 6-24 hours postexposure • Infuse at 1-1.5 mL/kg/hr adjusting postexposure as needed to maintain a urine flow rate of 150 mL/hr • Alternatively, in urgent cases, initiate infusion at 3 mL/kg/hr, beginning 1 hour prior to contrast exposure, then continue at 1 mL/kg/hr for 6 hours postexposure	A-1

[a] *Strength of recommendations*: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. *Quality of evidence*: (1) evidence from more than one properly randomized, controlled trial; (2) evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments; and (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Low-osmolar (600-800 mOsm/kg [mmol/kg]) nonionic (iohexol and iopamidol) and ionic (ioxaglate) contrast agents may be used to minimize the incidence of nephrotoxicity. Standard hyperosmolar contrast media (eg, low- and high-osmolar agent) are not reabsorbed in the kidney and cause osmotic diuresis, which contributes to the renal toxicity observed with these agents. Low-osmolar contrast agents have less than half the osmolality of high-osmolar (~2,000 mOsm/kg [mmol/kg]) agents and are associated with less toxicity, especially when used for patients with preexisting kidney disease.[37] However, use of low-osmolar agents does not preclude the development of nephrotoxicity. Even low-osmolar agents are hyperosmolar relative to plasma, which is likely the reason they have been associated with greater nephrotoxicity than the iso-osmolar nonionic contrast agent iodixanol. The relative differences in nephrotoxicity between the class of low-osmolar agents and iodixanol are unclear.[40,41]

Volume expansion and correction of dehydration prior to contrast administration is a mainstay of preventive therapy.[36] Parenteral hydration with isotonic saline before and after contrast administration reduces the incidence of toxicity, particularly in high-risk patients, and is the most widely accepted preventative intervention.[40] Volume expansion may exert its beneficial effects through dilution of contrast media, prevention of renal vasoconstriction, preservation of high urine flow rates, decreased tubular cell exposure to contrast, and avoidance of tubular obstruction. There is no benefit in using sodium bicarbonate or the thiol-containing antioxidant *N*-acetylcysteine over saline.[42] The guidelines recommend hydration with isotonic saline for CI-AKI prevention.[40,41] The use of oral hydration is also not recommended in lieu of parenteral hydration.[40,41]

Renal replacement therapy, including intermittent hemodialysis and continuous modalities, for example, continuous venovenous hemofiltration, effectively removes iodinated contrast, and was considered by some to be a therapeutic option for the prevention of CI-AKI. However, because of the logistical issues (eg, technical difficulty), potential infectious and noninfectious risks, high cost of renal replacement therapy, and lack of consistent clinical efficacy, renal replacement therapy is not recommended.[31,41]

Management

There is no specific therapy available for managing established CI-AKI. Other nephrotoxic drugs should be discontinued if possible, and subsequent contrast studies must be appropriately timed to minimize cumulative toxicity. Care is supportive as described in Chapter 61. Kidney function (eg, S_{cr} and urine output), electrolytes (eg, sodium and potassium), and volume status should be closely monitored.

Cisplatin Nephrotoxicity

Incidence

Cisplatin is one of the most important and widely used antineoplastic drugs for the treatment of solid tumors, often demonstrating exceptional efficacy (ie, cure rates over 90% in testicular cancers).[43] The primary dose-limiting toxicity of platin-containing compounds is nephrotoxicity. Cisplatin nephrotoxicity occurs in up to one-third of patients receiving the drug and is a significant cause of morbidity.[43,44] Carboplatin, a second-generation platinum analog, is associated with a lower incidence of nephrotoxicity than cisplatin and thus is the preferred agent in high-risk patients.[45]

Clinical Presentation

Cisplatin administration results in impaired tubular reabsorption and decreased urinary concentration ability, leading to increased excretion of salt and water (ie, polyuria) within 24 hours of treatment. Polyuria persists and a decrease in GFR evidenced by a rise in S_{cr} concentration may be seen within 72 to 96 hours after cisplatin administration.[46] S_{cr} peaks approximately 10 to 14 days after initiation of therapy, with recovery by 21 days.[47] As many as 25% of patients may have reversible elevations in S_{cr} and BUN for 2 weeks after cisplatin treatment. However, kidney damage is dose related and cumulative with subsequent cycles of therapy, so the S_{cr} concentration may continue to rise, and irreversible kidney injury may result.[45]

Hypomagnesemia is a hallmark finding of cisplatin nephrotoxicity, due to impaired magnesium reabsorption and thus increased urinary losses.[48] Hypomagnesemia is often accompanied by hypocalcemia and hypokalemia and may be severe, leading to seizures, neuromuscular irritability, or personality changes. Urinalysis typically reveals leukocytes, RTECs, and granular casts.

Pathogenesis

The pathogenesis of cisplatin nephrotoxicity is multifactorial in nature and likely begins with cellular uptake and accumulation of the drug in proximal tubular epithelial cells to concentrations that may reach five times the serum concentration.[49] Tubular cell exposure to cisplatin then activates a series of cell signaling pathways, including the mitogen-activated protein kinase pathway, p53, caspase, and the generation of reactive oxygen species, that collectively promote tubular cell injury and death via necrosis and/or apoptosis.[43,44] Simultaneous production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) within tubular cells activates an inflammatory response, which may worsen the renal insult. Although tubular damage is evident in both the proximal and distal segments, the majority occurs in the proximal tubules and is followed by a progressive loss of glomerular filtration capacity and impaired distal tubular function. Kidney biopsies generally reveal necrosis-apoptosis of proximal and distal tubules and collecting ducts, with no obvious morphological changes to the glomeruli.[47]

Risk Factors

Risk factors include age more than 65 years, dehydration, preexisting kidney disease, renal irradiation, concurrent use of nephrotoxic drugs, large cumulative doses, and alcohol abuse.[50]

Prevention

The best renoprotective strategy is a combination of interventions, including prospective dose reduction and decreased frequency of administration, which usually requires using the platin compounds in combination with other chemotherapeutic agents, avoiding concurrent use of other nephrotoxic drugs, and ensuring patients are euvolemic or somewhat hypervolemic prior to initiating treatment.[50,51] Vigorous hydration with isotonic saline should be used for all patients with a goal of maintaining at least 100 to 150 mL/hr of urine output during and after cisplatin treatment. Hydration should be initiated 12 to 24 hours prior to and continued for 2 to 3 days after cisplatin administration at rates of 100 to 250 mL/hr, as tolerated, to maintain a urine flow of 3 to 4 L/day.[46]

Amifostine, an organic thiophosphate that is converted to an active metabolite, chelates cisplatin in normal cells and reduces the nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression associated with cisplatin and carboplatin therapy. It is also thought to serve as a thiol donor, thereby reducing intracellular reactive oxygen species and corresponding oxidative stress that plays a critical role in the development of cellular injury.[44] Amifostine is Food and Drug Administration (FDA) approved to reduce nephrotoxicity associated with repeated cisplatin treatment in patients with advanced ovarian cancer. Pretreatment with amifostine should be considered for patients who are at high risk for kidney injury, particularly patients who are elderly, volume depleted, have CKD, or are receiving other nephrotoxic drugs concurrently. The recommended dose of amifostine is 910 mg/m^2 administered IV over 15 minutes, beginning 30 minutes prior to cisplatin administration. Common toxicities include acute hypotension, nausea, and fatigue.

Other renoprotective strategies include the use of hypertonic saline (eg, administration of each dose in 250 mL of 3% saline) to reduce tubular cisplatin uptake. Classic antioxidants such as ascorbic acid, thiol-based antioxidants such as α-lipoic acid and *N*-acetylcysteine, which reduce oxidative damage by acting as a sulfhydryl donor, and the disulfiram metabolite diethyldithiocarbamate to reduce cytochrome P450 2E1–mediated generation of hydroxyl radicals have also been evaluated.[49,52] Intravenous magnesium infusion has also been administered to prevent cisplatin-related AKI with mixed effects. Finally, reduced renal exposure can be achieved with the use of localized intraperitoneal administration in conjunction with systemic administration of sodium thiosulfate for those with peritoneal tumors.[46]

Management

AKI caused by cisplatin therapy is usually partially reversible with time and supportive care, including dialysis. Kidney function indices should be closely followed, with S_{cr} and BUN concentrations checked daily. Serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.[45] Hypocalcemia and hypokalemia may be difficult to reverse until hypomagnesemia is corrected. There is no role for dialysis to remove cisplatin. Progressive kidney disease caused by cumulative nephrotoxicity may be irreversible and in some cases may lead to ESKD and require chronic dialysis support.[45]

Amphotericin B Nephrotoxicity

Incidence

Variable rates of amphotericin B nephrotoxicity are seen that correspond in large part to the cumulative dose administered. Nephrotoxicity may be seen in nearly 30% of patients receiving median cumulative doses as low as 240 mg and reaches an incidence of greater than 80% when cumulative doses approach 5 g.[53–55] Although numerous studies demonstrate lower rates of nephrotoxicity with liposomal formulations compared with conventional amphotericin B, it is difficult to compare rates of toxicity between products and studies because of the variability in the study populations, doses administered, and inconsistent definitions of nephrotoxicity and methods of assessment.[53,54,56]

Clinical Presentation

Dose-dependent nephrotoxicity is often evident after administration of cumulative doses of 2 to 3 g as nonoliguria, renal tubular potassium, sodium, and magnesium wasting, impaired urinary concentrating ability, and distal renal tubular acidosis.[23,56] Although the cumulative dose is a significant risk factor, the time to onset of kidney injury varies considerably, ranging from a few days to weeks. Tubular dysfunction usually manifests 1 to 2 weeks after treatment is begun, and potassium and magnesium replacement may be necessary.[53] This is typically followed by a decrease in GFR and a rise in S_{cr} and BUN concentrations. Consequently, kidney function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations monitored every other day and corrected as needed.

Pathogenesis

Amphotericin B nephrotoxicity occurs predominantly via two mechanisms. The first is direct tubular epithelial cell toxicity resulting from interaction of amphotericin B with ergosterol in the cell membrane, leading to increased tubular cell membrane permeability, lipid peroxidation, and eventual necrosis of proximal tubular cells.[56] The second mechanism is afferent arteriolar vasoconstriction leading to a reduction in renal blood flow and GFR, and ischemic tubular injury.[23,56]

Risk Factors

Risk factors that impact the likelihood of developing amphotericin B nephrotoxicity include preexisting kidney disease, large individual and cumulative doses, short infusion times, volume depletion, hypokalemia, increased age, and concomitant administration of diuretics and other nephrotoxins, including vancomycin and cyclosporine.[53,56]

Prevention

Permanent decrements in GFR are best prevented by incorporating a low threshold (ie, if S_{cr} reaches 2 mg/dL [177 μmol/L] on 2 consecutive days) for stopping amphotericin B or switching to a liposomal formulation. Several lipid formulations of amphotericin B (eg, amphotericin B lipid complex, liposomal amphotericin B) are available and should be used in most high-risk patients as they reduce nephrotoxicity by enhancing drug delivery to sites of infection and reducing interaction with tubular epithelial cell membranes.[54,56] Nephrotoxicity can also be minimized by limiting the cumulative dose, increasing the infusion time, ensuring the patient is well hydrated, and avoiding concomitant administration of other nephrotoxins.[56] Administration of 1 L IV 0.9% sodium chloride daily during the course of therapy reduces toxicity and a single infusion of saline 10 to 15 mL/kg prior to administration of each dose of amphotericin B is generally recommended.[56] A number of other antifungal agents such as itraconazole, voriconazole, and caspofungin are viable alternatives and are now routinely used in lieu of amphotericin B for patients at high risk of developing nephrotoxicity. Administration of the antioxidant *N*-acetylcysteine (600 mg orally twice daily in adults) during amphotericin treatment may be nephroprotective.[57]

Management

Amphotericin B nephrotoxicity is best treated by discontinuation of therapy and substitution of alternative antifungal therapy, if possible. Renal tubular dysfunction and glomerular filtration will improve gradually to some degree in most patients, but damage may be irreversible. Kidney function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.

Osmotic Nephropathy

Several drugs, including mannitol, low-molecular-weight dextran, hydroxyethyl starch, and radiographic contrast media, or drug vehicles, such as sucrose, maltose, and propylene glycol, are associated with osmotic nephropathy, which may rarely lead to ATN and AKI.[58] Since osmotic nephropathy does not necessarily negatively affect proximal tubular function, its presence may often go undetected in patients without overt signs of ATN. This likely contributes to the extremely low incidence of osmotic nephropathy reported for causative agents. IV immunoglobulin solutions containing hyperosmolar sucrose may cause osmotic nephropathy and AKI in 1% to 10% of cases, which is usually reversible shortly after discontinuing therapy.[59,60] Maltose-based IV immunoglobulin solutions have also been implicated in the development of osmotic nephropathy. Although IV immunoglobulin-induced AKI is the modern prototype for osmotic nephropathy, the vehicle (ie, sucrose or maltose) is the culprit and not the immunoglobulins themselves.[60] The SGLT-2 inhibitors have been associated with a kidney lesion reminiscent of osmotic nephropathy. Presumably, the proximal tubule encounters massive glucose loads that are reabsorbed (SGLT-1 transporter) and overwhelm cellular metabolism, though this is rare.[61]

Clinical Presentation

The clinical presentation of osmotic nephropathy is often subtle. While tubular proteinuria or vacuolated tubular cells may be observed on urinalysis for patients with AKI, the definitive diagnosis of osmotic nephropathy is only made via a kidney biopsy.[59] IV immunoglobulin-induced AKI typically presents as oliguria after 2 to 4 days of treatment and may persist for up to 2 weeks. Kidney injury occurs via uptake of the offending agent through pinocytosis into proximal tubular epithelial cells, subsequent formation of vacuoles, and accumulation of lysosomes, which collectively results in an oncotic gradient and thus cellular swelling, tubular luminal occlusion, and compromised cellular integrity.[62] Renal replacement therapy may be necessary for up to 40% of patients developing osmotic nephropathy-associated AKI.[59] However, it is usually reversible, with nearly all patients recovering normal kidney function following withdrawal of the offending drug.

Risk Factors

Risk factors for osmotic nephropathy include excessive doses of offending agents, preexisting kidney disease, ischemia, older age (greater than 65 years), and concomitant use of other nephrotoxins. Nephrotoxicity may be prevented by limiting the dose, reducing the rate of infusion, and avoiding dehydration and concomitant nephrotoxins.[60,62]

HEMODYNAMICALLY MEDIATED KIDNEY INJURY

4 Hemodynamically mediated kidney injury generally refers to any cause of AKI resulting from an acute decrease in intraglomerular pressure, including "prerenal" states leading to reduced effective renal blood flow (eg, hypovolemia and congestive heart failure) and medications that affect the renin–angiotensin system (RAS).[23,63] The kidneys receive approximately 25% of resting cardiac output, which renders them particularly susceptible to alterations in renal blood flow and enhances their exposure to circulating drugs.[16,64] Within each nephron, blood flow and pressure are regulated by glomerular afferent and efferent arterioles to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration, and urine output. Afferent and efferent arteriolar vasoconstrictions are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins (Fig. 65-1). This specialized blood flow is precisely regulated by interrelations between arachidonic acid metabolites, natriuretic factors, nitric oxide, the sympathetic nervous system, the RAS, and the macula densa response to distal tubular solute delivery.[64] Drug-induced causes of hemodynamic kidney injury typically stem from constriction of glomerular afferent arterioles and/or dilation of glomerular efferent arterioles. ACEIs, angiotensin II receptor blockers (ARBs), and NSAIDs are the agents that have been most commonly implicated.[23,65] Capillary leak syndrome due to a severe cytokine release syndrome (CRS) is associated with hemodynamically mediated AKI with high-dose interleukin-2 and the chimeric antigen receptor (CAR) T-cells.[66]

FIGURE 65-1

Normal glomerular autoregulation serves to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration rate, and, ultimately, urine output. (A II, angiotensin II; PGE$_2$, prostaglandin E$_2$; RBF, renal blood flow.)

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

ACEIs and ARBs are extensively utilized for the management of hypertension and prevention of the progression of CKD even though they have been associated with the development of AKI.

Incidence

Patients with renal artery stenosis, volume depletion, and congestive heart failure and those with preexisting kidney disease, including diabetic nephropathy, are most likely to experience a significant decline in kidney function when therapy with one of these agents is initiated.[23] For example, up to 25% of hospitalized patients with congestive heart failure develop AKI within weeks after beginning treatment with ACEIs.[67] Moreover, ACEIs and ARBs are among the most commonly implicated medications in emergency hospitalizations, contributing to nearly 3% of emergency room visits for adverse drug events.[68]

Clinical Presentation

Therapy with ACEIs and ARBs will acutely reduce GFR; so a moderate rise in S_{cr} after initiation of therapy should be anticipated.[69] Importantly, a distinction must be made between a potentially detrimental reduction in GFR and a normal, predictable rise in S_{cr}. An increase in S_{cr} of up to 30% is commonly observed within 3 to 5 days of initiating therapy and is an indication that the drug has begun to exert its desired pharmacologic effect.[69] The increase in S_{cr} typically stabilizes within 1 to 2 weeks and is usually reversible upon stopping the drug. Furthermore, an association exists between acute increases in S_{cr} of less than or equal to 30% from baseline that stabilize within the first 2 months of initiating therapy and preservation of kidney function. The S_{cr} threshold for discontinuation of ACEI or ARB therapy is unclear. However, an increase in S_{cr} of more than 30% above baseline in the course of 1 to 2 weeks may necessitate discontinuation of the offending drug.[69]

Pathogenesis

ACEIs—or ARB-mediated kidney injury—is primarily the result of disruption of normal autoregulation of intraglomerular capillary hydrostatic pressure.[23] Normally, the kidney attempts to maintain GFR by dilating the afferent arteriole and constricting the efferent arteriole in response to a decrease in renal blood flow. During states of reduced blood flow, the juxtaglomerular apparatus increases renin secretion. Plasma renin converts angiotensinogen to angiotensin I, and ultimately angiotensin II by angiotensin-converting enzyme. Angiotensin II constricts the afferent and efferent arterioles, but has a greater effect on the efferent arterioles, resulting in a net increase in intraglomerular pressure.[64] Additionally, renal prostaglandins, prostaglandin E_2 in particular, are released and induce a net dilation of the afferent arteriole, thereby improving blood flow into the glomerulus. Together these processes maintain GFR and urine output (Fig. 65-2).

When ACEI therapy (eg, enalapril or ramipril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases hydrostatic pressure in the glomerular capillaries, which alters Starling forces across the glomerular capillaries to decrease intraglomerular pressure and GFR. This in turn often leads to nephrotoxicity, particularly in the setting of reduced renal blood flow or effective arterial blood volume (Fig. 65-3), that is, prerenal settings (eg, congestive heart failure) in which glomerular afferent arteriolar blood flow is reduced and the efferent arteriole is vasoconstricted to maintain sufficient glomerular capillary hydrostatic pressure for ultrafiltration.[23]

Risk Factors

Patients at greatest risk are those dependent on angiotensin II and renal efferent arteriolar constriction to maintain blood pressure and GFR. These include patients with bilateral renal artery stenosis or stenosis in a single kidney (ie, renal transplant); patients with decreased effective arterial blood volume (ie, prerenal states), especially those with decompensated congestive heart failure, volume depletion from excess diuresis or GI fluid loss, hepatic cirrhosis with ascites, and nephrotic syndrome; patients with preexisting kidney disease; and patients receiving concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation such as NSAIDs.[23,65,70]

Prevention

Hemodynamically mediated AKI caused by ACEIs or ARBs is frequently preventable by recognizing the presence of preexisting kidney disease or decreased effective renal blood flow as a result of volume depletion, heart failure, or liver disease. A common strategy for at-risk patients is to initiate therapy with low doses of a short-acting ACEI (eg, captopril 6.25-12.5 mg), then gradually titrate the dose upward, and convert to a longer-acting agent after patient tolerance has been demonstrated. Outpatients may be started on low doses of long-acting ACEIs (eg, enalapril 2.5 mg) with gradual dose titration every 2 to 4 weeks until the maximum dose or desired response is achieved.[69] Kidney function indices and serum potassium concentrations must be monitored carefully, daily for hospitalized patients and every 2 to 3 days for outpatients. Monitoring may need to be more frequent during outpatient initiation of ACEI or ARB therapy for patients with preexisting kidney disease, congestive heart failure, or suspected renovascular disease. Use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (eg, NSAIDs, diuretics) should be discouraged and dehydration avoided.[69]

Management

Acute decreases in kidney function and the development of hyperkalemia usually resolve over several days after ACEI or ARB therapy is discontinued. Occasionally patients will require management of severe hyperkalemia, as described in detail in Chapter 70, “Potassium and Magnesium Homeostasis.”

ACEIs or ARB therapy may frequently be reinitiated, particularly for patients with congestive heart failure, after intravascular volume depletion has been corrected or diuretic doses reduced. Slight reductions in kidney function (maintenance of a S_{cr} concentration of 2-3 mg/dL [177-265 µmol/L]) may be an acceptable trade-off for hemodynamic improvement in certain patients with severe congestive heart failure or renovascular disease not amenable to revascularization.

Nonsteroidal Anti-Inflammatory Drugs and Selective Cyclooxygenase-2 Inhibitors

The overall safety of NSAIDs is evidenced by the nonprescription availability in the United States of several drugs in the class (eg, ibuprofen, naproxen, ketoprofen). Although potential adverse renal effects from nonprescription NSAIDs had been a concern, conventional nonselective NSAIDs and selective cyclooxygenase-2 (COX-2) inhibitors are unlikely to acutely affect kidney function in the absence of renal ischemia or excess renal vasoconstrictor activity. Nevertheless, given their general safety and widespread availability, NSAIDs are among the most commonly used drugs, with approximately 111 million prescriptions worldwide and 30 billion over-the-counter doses of NSAIDs administered annually in the United States.[71]

Incidence

The incidence of NSAID-induced kidney injury is unclear. As many as 500,000 to 2.5 million people may develop some degree of NSAID nephrotoxicity in the United States annually.[72]

Clinical Presentation

NSAID- and COX-2-induced AKI usually occurs within 2 to 7 days of initiating therapy,[63,71] particularly with a short-acting agent such as ibuprofen, or within days of some other precipitating event (eg, intravascular volume depletion). Patients typically present with complaints of diminished urine output, weight gain, and/or edema. Urine sodium concentrations (less than 20 mEq/L [mmol/L]) and fractional excretion of sodium (less than 1% [0.01]) are usually low, and BUN, S_{cr}, potassium, and blood pressure are typically elevated. The urine sediment is usually bland and unchanged from baseline but may show occasional RTECs and granular casts.[63,71]

Pathogenesis

The pathogenesis of NSAID- and COX-2-induced AKI lies in the disruption of normal intraglomerular autoregulation.[63] Specifically, NSAIDs inhibit COX-catalyzed synthesis of vasodilatory prostaglandins, including prostaglandins I_2 (prostacyclin) and E_2, from arachidonic acid.[71] These prostaglandins are synthesized in the renal cortex and medulla by vascular endothelial and glomerular mesangial cells, and their effects are primarily local and result in net afferent arteriolar vasodilation. Vasodilatory prostaglandins have limited activity in states of normal renal blood flow, but in states of decreased renal blood flow, their synthesis is increased and they serve a vital autoregulatory role in the protection against renal ischemia and hypoxia by antagonizing renal arteriolar vasoconstriction due to angiotensin II, norepinephrine, endothelin, and vasopressin. Thus, administration of NSAIDs in the setting of reduced renal blood flow will blunt the usual compensatory increase in prostaglandin activity, altering the normal autoregulatory balance in favor of renal vasoconstrictors, thereby promoting renal ischemia and a reduction in glomerular filtration.[71]

Risk Factors

Risk factors for NSAID- and COX-2-induced AKI include age more than 60 years, preexisting kidney disease, hepatic disease with ascites, congestive heart failure, intravascular volume depletion/dehydration, systemic lupus erythematosus, or concurrent treatment with diuretics, ACEIs, or ARBs.[65,70,71] Use of ACEIs, diuretics, and NSAIDs concurrently is associated with a greater than 30% increased risk for AKI, which increases to greater than 60% in patients over age 75 or with preexisting kidney disease.[65,70] The elderly people are at higher risk because of multiple comorbidities, multiple-drug therapies, and reduced renal hemodynamics. Combined use of NSAIDs or COX-2 inhibitors and concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation, should be avoided in high-risk patients.

Prevention

NSAID- and COX-2 inhibitor–induced AKI can be prevented by recognizing high-risk patients, avoiding potent compounds such as indomethacin and using analgesics with less prostaglandin inhibition, such as acetaminophen, nonacetylated salicylates, aspirin, and possibly nabumetone. Nonnarcotic analgesics (eg, tramadol) may also be useful but do not provide anti-inflammatory activity. When NSAID therapy is essential for high-risk patients, the minimal effective dose should be used for the shortest duration possible, and NSAIDs with short half-lives should be considered (eg, sulindac) along with optimal management of predisposing medical problems and frequent kidney function monitoring. Moreover, use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (eg, ACEIs, ARBs, diuretics) should be discouraged in high-risk patients and dehydration avoided.[71]

Management

NSAID-induced AKI is treated by discontinuation of therapy and supportive care. Use of other nephrotoxic drugs should be avoided. Kidney injury is rarely severe, and kidney function generally recovers within 3 to 5 days.[63] Occasionally, the hemodynamic insult is sufficiently severe to cause ATN, which can prolong injury.

Cyclosporine and Tacrolimus

The calcineurin inhibitors cyclosporine and tacrolimus have dramatically enhanced the success of solid-organ transplantation. As many as 94% of kidney transplant patients are prescribed a calcineurin inhibitor–based immunosuppressive regimen.[73] Nephrotoxicity, however, remains a major dose-limiting adverse effect of both drugs. Although delayed chronic interstitial nephritis also is possible,[74] acute hemodynamically mediated kidney injury is an important mechanism of calcineurin inhibitor–induced nephrotoxicity.

Incidence

The reversible AKI occurred frequently in transplant recipients during the first 6 months of cyclosporine therapy. The five-year risk of CKD after transplantation of a nonrenal organ ranges from 7% to 21%, depending on the type of organ transplanted, and the occurrence of CKD in these patients is associated with more than a fourfold increase in the risk of death.[75]

Clinical Presentation

The clinical presentation of acute nephrotoxicity associated with calcineurin inhibitors (ie, hemodynamically mediated AKI) is quite different from the presentation of chronic nephrotoxicity (see "Chronic Interstitial Nephritis" section).[76] AKI may occur within days of initiating therapy, manifesting as a rise in S_{cr} concentration and a corresponding decline in creatinine clearance. Hypertension, hyperkalemia, sodium retention, oliguria, renal tubular acidosis, and hypomagnesemia are frequently observed in the absence of urine sediment abnormalities or morphologic lesions.[73] On the other hand, renal biopsy may reveal thickening of arterioles, mild focal glomerular sclerosis, proximal tubular epithelial cell vacuolization and atrophy, and interstitial fibrosis. Biopsy is most useful to distinguish acute calcineurin inhibitor nephrotoxicity from acute cellular rejection of the transplanted kidney, the latter being evidenced by interstitial infiltrates composed of activated lymphocytes (see Chapter 110, "Osteoarthritis").[77]

Pathogenesis

The acute hemodynamic changes associated with calcineurin inhibitor nephrotoxicity result from an increase in potent vasoconstrictors including thromboxane A_2 and endothelin, activation of the RAS and sympathetic nervous systems, as well as a reduction in the vasodilators nitric oxide, prostacyclin, and prostaglandin E_2.[73,75,76] The net effect is an imbalance in afferent and efferent tone, resulting in predominantly afferent vasoconstriction with reduced renal plasma flow and GFR. The mechanism of acute nephrotoxicity is generally thought to be dose related, since kidney function improves rapidly following dose reduction.[76]

Risk Factors

Risk factors include age over 65, higher dose, concomitant therapy with nephrotoxic drugs (particularly NSAIDs), and interacting drugs that inhibit calcineurin inhibitor metabolism and transport and thus increase systemic exposure, older kidney allograft age, salt depletion, diuretic use, and polymorphic expression of P-glycoprotein.[73,77]

Prevention

Because acute hemodynamically mediated kidney injury secondary to cyclosporine and tacrolimus is concentration related, pharmacokinetic and pharmacodynamic monitoring is an important means of preventing toxicity.[73] However, the persistent presence of therapeutic or low cyclosporine concentrations does not totally preclude the development of nephrotoxicity. Calcium channel blockers may antagonize the vasoconstrictor effect of cyclosporine by dilating glomerular afferent arterioles and preventing acute decreases in renal blood flow and glomerular filtration.[73] Lastly, decreased doses of cyclosporine or tacrolimus, primarily when used in combination with other nonnephrotoxic immunosuppressants, may minimize the risk of toxicity, but this may increase the risk of chronic rejection.

Management

AKI usually improves with dose reduction and treatment of contributing illness or the discontinuation of interacting drugs. CKD is usually irreversible, but progressive toxicity may be limited by discontinuation of cyclosporine (or tacrolimus) therapy or dose reduction, with the continuation of other immunosuppressants.[73,76] S_{cr} and BUN should be closely monitored (daily if possible), as should cyclosporine or tacrolimus concentrations, to ensure that serum concentrations are within the narrow therapeutic range.

SGLT-2 Inhibitors

The sodium-glucose co-transporter-2 (SGLT-2) inhibitors (eg, empagliflozin, canagliflozin, dapagliflozin) are now being employed frequently to enhance serum glucose control in patients with type 2 diabetes mellitus.[78] SGLT-2 inhibitor drugs are nephroprotective.[79,80] As such, they are FDA approved and now used in addition to metformin to help with glucose control in patients with type 2 diabetes mellitus. The estimated GFR cutoffs for use of these drugs is <60 mL/min/1.73 m^2 for dapagliflozin and <45 mL/min/1.73 m^2 for empagliflozin and canagliflozin. However, AKI is one complication of canagliflozin and dapagliflozin that has been reported to the FDA Adverse Event Reporting System (FAERS). This led the FDA to issue an FDA Drug Safety Communication, http://www.fda.gov/downloads/Drugs/DrugSafety/UCM506772.pdf, for these two SGLT-2 inhibitors.

Incidence

There is no estimated incidence of AKI available for these drugs. However, over 100 cases of AKI associated with the SGLT-2 inhibitors have been reported to FAERS. This contrasts with the randomized controlled trials that do not note AKI as a complication of these drugs.[79,80] In addition, a propensity-matched analysis also showed no signal for AKI with these drugs.[81]

Pathogenesis

The increase in S_{cr} and development of AKI are likely related to a number of processes. As these drugs induce glucosuria due to inhibition of proximal tubular glucose reabsorption, they induce an osmotic diuresis (natriuresis) that can lead to volume depletion, especially when used along with diuretics. SGLT-2 inhibitor related volume depletion in the setting of RAS blocker therapy (ie, ACEI or ARB therapy) can lead to prominent hemodynamic (prerenal) AKI. When severe, acute tubular injury may develop leading to a classic form of ATN. In addition, the delivery of sodium chloride to the macula densa also induces a phenomenon known as tubuloglomerular feedback, which vasoconstricts glomerular afferent arterioles and reduces GFR, ultimately causing an increase in S_{cr}. The increase in S_{cr} may be interpreted by clinicians as indicative of AKI. However, over the long term, this effect is thought to be one of the major nephroprotective mechanisms of the SGLT-2 inhibitors by reducing hyperfiltration-related injury. The SGLT-2 inhibitors may cause direct tubular injury. Uricosuria induced by these drugs may cause both crystal-related tubular injury (crystal nephropathy) and crystal-independent mechanisms of injury.[82] Also, increased urinary glucose may promote intratubular oxidative stress by activating aldose reductase and sorbitol and fructose generation.[82]

Risk Factors

According to the FAERS reports, many patients developing AKI with these drugs were older, were also treated with RAS blockers and diuretics, and sometimes were also taking other nephrotoxins such as NSAIDs. Clearly, combining these drugs with the SGLT-2 inhibitors may lead to AKI when volume depletion occurs. Also, concurrent illness that leads to volume depletion (nausea, vomiting, diarrhea) may also increase risk for AKI.

Prevention

Prevention of AKI in patients with type 2 diabetes mellitus taking these drugs requires careful follow-up in patients who are also taking RAS blockers and diuretics. Patients should be counseled to avoid other nephrotoxins, in particular NSAIDs and COX-2 inhibitors, and contact their care provider when a concurrent illness develops. This will allow timely adjustment of the medications.

Management

When AKI develops, stopping the SGLT-2 inhibitor often is enough to allow kidney recovery. However, in patients with volume depletion on exam, holding the SGLT-2 inhibitor (and RAS blocker and diuretic if also prescribed) and giving intravenous fluids typically resolve AKI. In cases where ATN develops, the SGLT-2 inhibitor should be held and usual supportive care, including RRT when required, should be undertaken. The SGLT-2 inhibitor can likely be restarted in patients where kidney function recovers to baseline and eGFR is above the FDA-recommended threshold.

Chimeric Antigen Receptor T-Cells

Incidence

CAR T-cell therapy is a highly efficacious immunotherapy that employs the principle of adoptive cell transfer. T-cells are collected from patients and re-engineered to express selective tumor-targeted receptors (CARs) on cell surfaces. CARs function irrespective of any major histocompatibility complex restriction, making them immune to any T-cell evading mechanisms of tumor cells. The CAR T-cell therapy tisagenlecleucel is a CD-19 targeted therapy for B-cell acute lymphoblastic leukemia while axicabtagene ciloleucel is used to treat large B-cell lymphoma and brexucabtagene autoleucel is employed for relapsed/refractory mantle cell lymphoma.[83,84] CAR T-cell therapy is complicated by severe systemic inflammatory disorders that lead to AKI in 18.6% of patients, with up to 4.4% of patients developing AKI requiring dialysis.[85]

Pathogenesis

One of the most common toxicities observed with CAR-T therapy is CRS, which is characterized by high fever, hypotension, hypoxia, and multi-organ toxicity including AKI. CRS is triggered by a surge of cytokines and chemokines released by activated T-cells and by bystander immune cells. CRS typically manifests in the first week (median 2-3 days) after the CAR T-cell infusion and peaks within 1 to 2 weeks.[86] Patients at highest risk have bulky disease and multiple comorbidities. AKI is due to primarily to either hemodynamic (prerenal) kidney dysfunction or ischemic acute tubular injury (with severe hypotension and high grade CRS). Cytokine-mediated kidney injury, hemophagocytic lymphohistiocytosis (hyperactivation of lymphocytes and macrophages), and tumor lysis syndrome may also play a role, but have not been verified with kidney biopsy evidence. Infectious complications with sepsis and nephrotoxic medications (antibiotics, NSAIDs, etc.) may also contribute to AKI in these patients.[66,86]

Management

Management of AKI from CAR T-cell treatment is primarily focused on the severity (grade) of CRS with the overall goal to balance treatment of CRS complications and end-organ injury with beneficial effects of the anti-cancer therapy. Supportive care includes vasopressors and intravenous fluids for hypotension, while anti–interleukin-6 therapy with tocilizumab or siltuximab with/without corticosteroids is used for severe CRS.[66,86]

OBSTRUCTIVE NEPHROPATHY

Numerous medications may cause obstructive nephropathy, or kidney injury from deposition or precipitation within the renal tubules and/or collecting system. For example, the precipitation of drug crystals in distal tubular lumens can lead to intratubular obstruction, interstitial nephritis, and occasionally superimposed ATN, collectively termed “crystal nephropathy.” Nephrolithiasis, the formation of stones within the kidney, results from abnormal crystal precipitation in the renal collecting system, potentially causing urinary tract obstruction with kidney injury. Several medications that have been associated with development of obstructive nephropathy are listed in Table 65-1.

Crystal Nephropathy

Incidence

The incidence of crystal nephropathy is unclear for most of the implicated agents because histologically confirmed cases are rare, and many drugs cause kidney injury via multiple mechanisms.[87] For example, AKI develops in approximately 2% of patients who receive high-dose methotrexate, likely due to a combination of direct toxic effects and crystal nephropathy.[88,89] Similarly, crystalluria is observed in 20% of patients receiving indinavir, but the number of patients developing crystal nephropathy is unknown.[90]

Pathogenesis

Drugs may induce intratubular obstruction and AKI by direct (precipitation of the drug itself) and indirect means (ie, promoting release and precipitation of tissue-degradation products or cellular casts). For example, antineoplastic drugs may cause acute renal tubular obstruction indirectly by inducing tumor lysis syndrome, hyperuricemia, and intratubular precipitation of uric acid crystals.[50] The diagnosis is supported by a urine uric acid-to-creatinine ratio greater than 1. Uric acid precipitation can be prevented by vigorous hydration with normal saline, beginning at least 48 hours prior to chemotherapy, to maintain urine output 100 mL/hr in adults. Administration of allopurinol 100 mg/m^2 thrice daily (maximum of 800 mg/day) started 2 to 3 days prior to chemotherapy, and urinary alkalinization to pH 7 may also be of value. In patients at high risk of developing tumor lysis syndrome (ie, large tumor burden, preexisting kidney disease, and older age), a single fixed dose of 3 mg rasburicase may be beneficial.[91]

Drug-induced rhabdomyolysis is another form of indirect toxicity, which can lead to intratubular precipitation of myoglobin and, if severe, AKI.[92] The most common cause of drug-induced rhabdomyolysis is direct myotoxicity from 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors or statins, including lovastatin and simvastatin.[93] The risk of rhabdomyolysis is increased when these drugs are administered concurrently with gemfibrozil, niacin, or inhibitors of the CYP3A4 metabolic pathway (eg, erythromycin and itraconazole).

Anticoagulant nephropathy, including warfarin-related nephropathy, is characterized by glomerular hemorrhage with subsequent intratubular obstruction by red blood cell casts. Patients with underlying CKD appear to be at greatest risk. The incidence of warfarin-related nephropathy may be as high as 33% in CKD versus 16.5% in non-CKD patients. Other risk factors included age, diabetes mellitus, hypertension, and cardiovascular disease.[94]

Intratubular precipitation of drugs or their metabolites can also directly cause AKI. Precipitation of drug crystals is due primarily to supersaturation of a low urine volume with the offending drug or relative insolubility of the drug in either alkaline or acidic urine.[90] Volume depletion is an important risk factor for the development of AKI. Urine pH decreases to approximately 4.5 during maximal stimulation of renal tubular hydrogen ion secretion. Certain solutes can precipitate and obstruct the tubular lumen at this acid pH, particularly when urine is concentrated, such as for patients with volume depletion. For example, several antiviral drugs have been associated with intratubular precipitation and AKI.[95,96] Acyclovir is relatively insoluble at physiologic urine pH and is associated with intratubular precipitation in dehydrated oliguric patients.[90] Foscarnet complexation with ionized calcium may result in precipitation of calcium-foscarnet salt crystals in renal glomeruli, causing primarily a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis.[23] The protease inhibitors indinavir and atazanavir have been associated with symptomatic crystalluria or nephrolithiasis in 20% to 33% of patients receiving chronic treatment.[90,96] Intratubular indinavir or atazanavir crystal precipitation can be prevented in most patients if the patient consumes adequate hydration to obtain a urinary output of at least 1,500 mL/day.[95] Sulfadiazine, when used at high doses, and methotrexate may also precipitate in acidic urine and can cause oligoanuric kidney injury.[90] Massive administration of ascorbic acid can also result in obstruction of renal tubules with calcium oxalate crystals, leading to "oxalate nephropathy."[90] Triamterene and the quinolone antibiotic ciprofloxacin may also precipitate in renal tubules and cause kidney injury.[23,87]

Kidney injury caused by intratubular precipitation of most tissue-degradation products or drugs and their metabolites can be largely prevented and possibly treated by administering the drug after vigorously prehydrating the patient, maintaining a high urine volume, and urinary alkalinization.[95,96]

Vancomycin Cast Nephropathy

Vancomycin-associated AKI may also be due to the formation of obstructive tubular casts composed of noncrystal nanospheric vancomycin aggregates admixed with uromodulin.[97] These distinctive casts are observed in some patients with AKI associated with high vancomycin trough concentrations. On kidney biopsy, acute tubulointerstitial inflammation is associated with these tubular casts. Co-precipitation of vancomycin and uromodulin occurs.[98]

Acute Phosphate Nephropathy

Nephrocalcinosis is a clinical pathologic condition characterized by extensive tubulointerstitial precipitation and deposition of calcium phosphate crystals leading to marked tubular calcification.[99] It is most commonly seen in clinical conditions associated with hypercalcemia and hypercalciuria, such as hyperparathyroidism, malignancy, and less frequently increased intake of calcium or vitamin D. However, nephrocalcinosis can also result from hyperphosphatemia and hyperphosphaturia in the absence of hypercalcemia, as is known to occur for patients who have received oral sodium phosphate solution (OSPS) as a bowel preparation.[100]

The term "acute phosphate nephropathy" was coined specifically to describe OSPS-induced nephrocalcinosis, as its pathogenesis is the result of increased phosphate intake rather than hypercalcemia.[100] Nephrocalcinosis is associated with use of OSPS for bowel preparation prior to GI procedures, and strong associations are present between exposure to OSPS and a decline in kidney function, particularly in the elderly and those with preexisting kidney disease.[100,101]

Incidence

The incidence of acute phosphate nephropathy is between 1 in 1,000 and 1 in 5,000 exposures, translating to roughly 1,400 to 7,000 new cases annually.[102]

Clinical Presentation

Patients usually present with AKI several days to months after exposure to OSPS. Low-grade proteinuria (less than 1 g/day), normocalcemia, and bland urinary sediment are usually observed. Extensive deposition of calcium phosphate in the distal tubules and collecting ducts without glomerular or vascular injury is the hallmark of acute phosphate nephropathy.[90]

Risk Factors

Risk factors include advanced age, preexisting kidney disease, female sex, hypertension, diabetes, bowel conditions associated with prolonged intestinal transit, high sodium phosphate dosage, volume depletion, and medications that affect renal perfusion or function (eg, diuretics, lithium, NSAIDs, ACEIs, or ARBs).[100]

Nephrolithiasis

Nephrolithiasis (formation of renal calculi or kidney stones) does not present as classic nephrotoxicity since GFR is usually not decreased. Drug-induced nephrolithiasis can be the result of abnormal crystal precipitation in the renal collecting system, potentially causing pain, hematuria, infection, or, occasionally, urinary tract obstruction with kidney injury. The overall prevalence of drug-induced nephrolithiasis is about 1% to 2% of all cases of nephrolithiasis.[96]

Kidney stone formation, possibly also accompanied by intratubular precipitation of crystalline material, has been a rare complication of drug therapy. Until the development of antiretroviral drugs, triamterene had been the drug most frequently associated with kidney stone formation, with a prevalence of 0.4%.[87] Sulfadiazine is a poorly soluble sulfonamide that may cause symptomatic acetylsulfadiazine crystalluria with stone formation and flank or back pain, hematuria, or kidney injury.[90] A high urine volume and urinary alkalinization to pH greater than 7.15 may be protective. Numerous other drugs have been implicated in the development of nephrolithiasis, including the antibacterial agents ciprofloxacin, amoxicillin, and nitrofurantoin, and various products containing ephedrine, norephedrine, pseudoephedrine, and melamine. Moreover, nephrolithiasis has become a well-known complication of antiretroviral agents, including the protease inhibitors indinavir, atazanavir, nelfinavir, amprenavir, saquinavir, ritonavir, and darunavir.[96]

GLOMERULAR DISEASE

Proteinuria, particularly nephrotic range proteinuria (defined as urine protein excretion greater than 3.5 g/day) with or without a decline in the GFR is a hallmark sign of glomerular injury (see Chapter e66, "Glomerulonephritis"). Glomerular injury associated with drug exposure is broadly classified into either direct cellular toxicity or immune-mediated injury. Glomerular lesions associated with direct cellular toxicity include thrombotic microangiopathy (see "Renal Vasculitis" section), minimal change glomerular disease, and focal segmental glomerulosclerosis (FSGS). Lesions from immune-mediated injury include vasculitis (see "Renal Vasculitis" section) and membranous nephropathy.[103,104] Although drug-induced glomerular disease is uncommon, a variety of agents have been implicated.

Minimal Change Glomerular Disease

Drug-induced minimal change glomerular disease is frequently accompanied by interstitial nephritis and is most common during NSAID therapy. Lithium, pamidronate, interferon-α, and interferon-β have also been implicated.[103] Patients present abruptly with nephrotic range proteinuria, hypoalbuminemia, and hyperlipidemia and rarely with hematuria and hypertension. The pathogenesis is unknown, but nephrotic range proteinuria as a consequence of NSAID therapy is frequently associated with a T-lymphocytic interstitial infiltrate, suggesting disordered cell-mediated immunity.[71] Proteinuria usually resolves rapidly after discontinuation of the offending drug, and a course of corticosteroids (eg, prednisone) may help resolve the lesion. That said, the majority of adults with NSAID-induced minimal change glomerular disease achieve complete remission over the course of several months, even in the absence of corticosteroid treatment.[103]

Focal Segmental Glomerulosclerosis

FSGS is characterized by patchy areas (ie, only some glomeruli are partially affected by the disease) of glomerular sclerosis with interstitial inflammation and fibrosis (see Chapter e66). It represents a pattern of glomerular injury, not a disease per se, and is the final common pathway by which normal glomerular components are replaced by fibrous scar tissue. FSGS has been described in the setting of chronic heroin abuse (known as *heroin nephropathy*).[105] The pathogenesis is unknown but may include direct toxicity by heroin or adulterants and injury from bacterial or viral infections accompanying IV drug use. The bisphosphonates pamidronate and zoledronate, commonly used to treat osteoporosis, malignancy-associated hypercalcemia, and Paget's disease, are associated with the development of a particularly aggressive variant of FSGS called *collapsing glomerulopathy*.[103] It presents with massive proteinuria (greater than 8 g/day), and it is typically characterized by rising S_{cr} at diagnosis and rapid progression to ESKD. Patients receiving IV formulations, high doses, or prolonged therapy are at highest risk. Interferon-α, interferon-β, lithium, sirolimus, and anabolic steroids have also been associated with FSGS.

Membranous Nephropathy

Membranous nephropathy is the most common etiology of nephrotic syndrome in Caucasian adults.[104] It is characterized by subepithelial immune complex formation along glomerular capillary loops and, although rarely seen, has classically been associated with gold therapy, penicillamine, captopril, and NSAID use.[104] Patients present with nephrotic range proteinuria and microscopic hematuria, with hypertension and elevated S_{cr} apparent for patients with more advanced disease. The pathogenesis may involve damage to proximal tubule epithelium with antigen release, antibody formation, and glomerular immune complex deposition.[104] Proteinuria usually resolves slowly after discontinuing the offending drug. Patients who remain nephrotic after 6 months should be treated with a 6- to 12-month course of immunosuppressive therapy, which typically consists of prednisone with or without cyclophosphamide.

TUBULOINTERSTITIAL NEPHRITIS

Tubulointerstitial nephritis refers to diseases in which the predominant changes occur in the renal interstitium rather than the tubules. The presentation may be acute and reversible with interstitial edema, rapid loss of kidney function, and systemic symptoms or chronic and irreversible, associated with interstitial fibrosis and minimal to no systemic symptoms.[106]

Acute Allergic Interstitial Nephritis

Incidence

⑤ The incidence of drug-induced acute allergic interstitial nephritis (AIN) is unclear and likely varies with clinical setting. For example, pathology registries indicate AIN as the histologic lesion in only 2% to 5% of kidney biopsies, but from 10% to 27% of kidney biopsies performed in hospitalized patients with unexplained AKI demonstrate AIN.[63] Multiple drugs have been implicated in the development of AIN (Table 65-4). It usually manifests 2 weeks after exposure to a drug but may occur sooner if the patient was previously sensitized.[107]

TABLE 65-4

Drugs Associated with Allergic Interstitial Nephritis

Antimicrobials	
Acyclovir	Indinavir
Aminoglycosides	Rifampin
Amphotericin B	Sulfonamides
β-Lactams	Tetracyclines
Ciprofloxacin	Trimethoprim–sulfamethoxazole
Ethambutol	Vancomycin
Diuretics	
Acetazolamide	Loop diuretics
Amiloride	Triamterene
Chlorthalidone	Thiazide diuretics
Neuropsychiatric	
Carbamazepine	Phenytoin
Lithium	Valproic acid
Phenobarbital	
Nonsteroidal anti-inflammatory drugs	
Aspirin	Ketoprofen
Indomethacin	Phenylbutazone
Naproxen	Diclofenac
Ibuprofen	Zomepirac
Diflunisal	Cyclooxygenase-2 inhibitors
Piroxicam	
Miscellaneous	

Acetaminophen	Immune checkpoint inhibitors
Allopurinol	Lansoprazole
Interferon-α	Methyldopa
Aspirin	Omeprazole
Azathioprine	P-aminosalicylic acid
Captopril	Phenylpropanolamine
Cimetidine	Propylthiouracil
Clofibrate	Radiographic contrast media
Cyclosporine	Ranitidine
Glyburide	Sulfinpyrazone
Gold	Warfarin sodium

Clinical Presentation

Although methicillin-induced AIN is the prototype for AIN, AIN is associated with all β-lactam antibiotics (including cephalosporins) and numerous other antimicrobials. Clinical signs present approximately 14 days after initiation of therapy and include (with their approximate incidence) fever (27%-80%), maculopapular rash (15%-25%), eosinophilia (23%-80%), arthralgia (45%), and oliguria (50%).[107] The systemic hypersensitivity findings of the classic triad of fever, rash, and arthralgia, often along with eosinophilia and eosinophiluria, supported the diagnosis of AIN. However, this constellation of findings is not consistently reliable as one or more are frequently absent. In fact, the triad is seen in only 5% to 10% of patients with AIN, so caution is warranted in basing diagnosis on hypersensitivity findings alone.[108] Eosinophilia alone is insensitive, and eosinophiluria is insensitive and nonspecific, so urinary eosinophils are not considered a useful sign of AIN and are no longer recommended as a diagnostic test.[108] Anemia, leukocytosis, and elevated immunoglobulin E levels may occur. Tubular dysfunction may be manifested by acidosis, hyperkalemia, salt wasting, and concentrating defects.[107]

Nonsteroidal Anti-Inflammatory Drugs

NSAID-induced AIN has a different clinical presentation than that seen with most other drugs. Patients are typically over 50 years of age (reflecting NSAID use for degenerative joint disease), the onset is delayed a mean of 6 months from initiation of therapy compared with 2 weeks with β-lactams, and fever, rash, and eosinophilia are typically not observed in patients with NSAID-induced AIN.[100] Concomitant nephrotic syndrome (proteinuria greater than 3.5 g/day) occurs in more than 70% of patients. Prompt diagnosis of AIN is important as discontinuation of the offending drug may prevent irreversible renal damage. Renal biopsy is the most definitive method for diagnosis.

Proton Pump Inhibitors

The proton pump inhibitors (PPIs) are widely prescribed to treat acid-related gastrointestinal disease. While they are generally well tolerated and safe, AIN is a complication and it may lead to AKI, and rarely to CKD.[109] In contrast to the classic allergic presentation of AKI seen with the β-lactams, fever, rash, and eosinophilia are rarely seen with PPIs. In addition, the latent period from PPI exposure to AIN is much longer (weeks to months). Kidney biopsy is often required to definitively diagnose PPI-related AIN due to the lack of diagnostic clinical and laboratory findings.[110]

Immune Checkpoint Inhibitors

Immune checkpoint inhibitors are a novel class of cancer immunotherapy noted to be associated with AKI, which is due primarily to AIN.[66,111,112] The incidence of AKI associated with these drugs ranges between 1% and 5%, with kidney biopsy showing AIN in more than 80% of patients.[111] These drugs (monoclonal antibodies) target immune pathways, including the receptors cytotoxic T-lymphocyte antigen-4 (CTLA-4), programmed cell death protein-1 (PD-1), and the T-cell receptor ligand (PD-ligand-1), that dampen T-cell activation and effector responses to prevent autoimmunity. Cancer cells, however, use these pathways to escape targeting by the immune system. In inhibiting such pathways, immune checkpoint inhibitors stimulate T-cell responses against cancer cells. Off-target organ injury, termed "immune-related adverse events," including AIN has been described. AIN has been observed in patients receiving anti-PD-1 agents either as monotherapy or in combination with anti-CTLA-4 drugs.[66,111,112] The mechanism underlying immune checkpoint inhibitor–associated AIN is unknown, but may be similar to the previously described mechanisms behind AIN from other drugs. Immune checkpoint inhibitors may also favor development of autoantibodies or encourage a pro-inflammatory cytokine milieu.[66] Patients may present with either other immune-related adverse events or no symptoms. Clinical findings such as rash and eosinophilia may not be encountered, while laboratory tests such as pyuria and white blood cell casts are present only occasionally. Diagnosis of immune checkpoint inhibitor–associated AIN generally requires kidney biopsy.

Pathogenesis

The pathogenesis of the majority of cases of AIN is considered to be an allergic hypersensitivity response. This is supported by the fact that AIN is characterized as a diffuse or focal interstitial infiltrate of lymphocytes, eosinophils, and occasional polymorphonuclear neutrophils.[106] Granulomas and tubular epithelial cell necrosis are relatively common with drug-induced AIN. Occasionally a humoral antibody-mediated mechanism is implicated by the presence of circulating antibody to a drug hapten–tubular basement membrane complex, low serum complement levels, and deposition of immunoglobulin G and complement in the tubular basement membrane. More commonly, a cell-mediated immune mechanism is suggested by the absence of these findings and the presence of a predominantly T-lymphocyte.[106]

Risk Factors

Despite this being an idiosyncratic hypersensitivity reaction, recent studies suggest that underlying CKD, receipt of drugs such as PPIs and NSAIDs, and combination immune checkpoint inhibitor therapy increase risk for AKI.[111] Individuals with other drug allergies may have increased risk and warrant close monitoring.

Prevention

No specific preventive measures are known because of the idiosyncratic nature of these reactions. Patients must be monitored carefully to recognize the signs and symptoms because promptly discontinuing the offending drug often leads to full recovery.[107]

Management

Corticosteroid therapy may be beneficial and should be initiated immediately or soon after diagnosis of AIN along with discontinuance of the offending drug to avoid the risk of incomplete recovery of kidney function. While various regimens have been used, high-dose oral prednisone 1 mg/kg/day for 4 to 6 weeks with a stepwise taper over the next 4 weeks may be considered. However, if there is no significant improvement in kidney function after 3 to 4 weeks of treatment, then steroids should be discontinued.[106] Typical kidney function indices (eg, S_{cr}, BUN) and signs and symptoms of AIN should be monitored closely for improvement. In PPI-induced AIN, drug discontinuation and corticosteroids are effective in most but not all cases, with CKD occurring in a significant number.[109] Management of immune checkpoint inhibitor–associated AIN generally includes drug discontinuation and corticosteroids, although recommendations on dose and duration are lacking.[66] Rechallenge with an immune checkpoint inhibitor is associated with recurrent AKI in approximately 23% of patients.[111]

Chronic Interstitial Nephritis

Lithium, analgesics, calcineurin inhibitors, aristolochic acid, and only a few other drugs cause chronic interstitial nephritis, which is usually a progressive and irreversible lesion.

Lithium

Incidence

The prevalence of non-dialysis-dependent CKD stemming from chronic lithium nephrotoxicity in the general population of patients treated with lithium is approximately 1%.[113,114] The prevalence of lithium-induced ESKD among all ESKD patients is between 0.2% and 0.8%.[113] Although several renal tubular lesions are associated with lithium therapy, an impaired ability to concentrate urine (nephrogenic diabetes insipidus) is seen in 20% of all patients receiving lithium therapy.[115]

Clinical Presentation

Lithium-induced nephrotoxicity is typically asymptomatic and develops insidiously during years of therapy. Blood pressure is normal and urinary sediment is bland, making detection difficult until the disease progresses significantly.[116] It is usually recognized by rising BUN or S_{cr} concentrations or the onset of hypertension. Polydipsia (excessive thirst) and polyuria (excessive urination) are observed in 40% and 20%, respectively, of patients with nephrogenic diabetes insipidus (see Chapter 68, “Disorders of Sodium and Water Homeostasis”). Although interstitial fibrosis may be observed as early as five years after beginning therapy, lithium-induced CKD usually occurs after 10 to 20 years of lithium treatment.[116]

Pathogenesis

The precise mechanism of chronic lithium-induced nephrotoxicity is not well characterized. Impaired ability to concentrate urine is a result of a decrease in collecting duct response to antidiuretic hormone, which may be related to downregulation of aquaporin 2 water channel expression during lithium therapy.[116] Chronic tubulointerstitial nephritis attributed to lithium is evidenced most commonly by kidney biopsy findings of interstitial fibrosis, tubular atrophy, tubular microcysts, and glomerular sclerosis. The tubular microcysts can sometimes be visualized on imaging studies such as MRI. The pathogenesis may involve cumulative direct lithium toxicity, since duration of therapy correlates with the decline in the GFR.[116]

Risk Factors

The duration of lithium therapy and cumulative dose was considered the major determinants of chronic nephrotoxicity. However, this is now questionable, as long-term lithium therapy in the absence of episodes of acute intoxication may not be nephrotoxic.[117] Increased age may also be a risk factor, but daily dose is not.[114,116]

Prevention

Prevention of acute and chronic toxicity includes maintaining lithium concentrations as low as therapeutically possible, avoiding dehydration, and monitoring kidney function. It is unknown whether progression to CKD can be prevented by stopping lithium use when mild kidney injury is first recognized. This poses a dilemma as lithium is highly effective for affective disorders and the risks and potential benefits of discontinuing such a beneficial drug need to be carefully considered.[116] However, if lithium therapy is continued, kidney function must be monitored and therapy discontinued if it continues to decline. Amiloride has been used for prevention and treatment of lithium-induced nephrogenic diabetes insipidus, since it blocks epithelial sodium transport of lithium into the cortical collecting duct in the distal nephron.[116]

Management

Symptomatic polyuria and polydipsia can be reversed by discontinuation of lithium therapy or ameliorated with amiloride 5 to 10 mg daily during continued lithium therapy (see Chapter 68). If polyuria does not resolve within 7 to 10 days of therapy, then the amiloride dose should be increased to 20 mg daily. Progressive chronic interstitial nephritis is treated by discontinuation of lithium therapy, adequate hydration, and avoidance of other nephrotoxic agents. Lithium serum concentrations, as well as kidney function indices, including urine output, BUN, and S_{cr}, should be monitored closely for resolution of signs and symptoms of toxicity.[116]

Cyclosporine and Tacrolimus

Delayed chronic tubulointerstitial nephritis, considered the Achilles' heel of calcineurin inhibitor–based immunosuppressive regimens, may occur after several months of therapy and can result in irreversible kidney disease.[73,74] Toxicity is progressive and usually manifests as a slowly rising S_{cr} concentration and decreased creatinine clearance that may not reflect the severity of histopathologic changes. All three compartments of the kidney can be affected, evidenced by typical biopsy findings that include arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis.[74] The pathogenesis involves sustained renal arteriolar endothelial cell injury and increased extracellular matrix synthesis, which ultimately result in chronic ischemia of the tubulointerstitial compartment because of increased release of endothelin-1, decreased production of nitric acid, and upregulation of transforming growth factor-β. Unlike acute nephrotoxicity, chronic toxicity is not dose dependent.[73,74]

Aristolochic Acid

Incidence

Although the true incidence of aristolochic acid nephropathy is unknown, approximately 3% to 5% of patients who consume the natural product develop interstitial fibrosis with tubular atrophy.[118]

Clinical Presentation

Patients with aristolochic acid nephropathy typically present with mild-to-moderate hypertension, mild proteinuria, glucosuria, and moderately elevated S_{cr} concentrations. Anemia and shrunken kidneys are also common on initial presentation.[119] The overwhelming majority of cases to date have been in women. The main pathologic lesions observed in the kidneys are interstitial fibrosis with atrophy and destruction of proximal tubules throughout the renal cortex; in general, the glomeruli are not affected. Perhaps the most remarkable feature of aristolochic acid nephropathy is the rate at which it progresses. In most individuals, ESKD requiring dialysis or transplantation develops within 6 to 24 months of exposure. An alarming high prevalence (approximately 40%-45%) of urothelial transitional cell carcinoma has been observed in Belgian patients who underwent renal transplantation.[118,119]

Pathogenesis

The precise mechanism of aristolochic acid nephropathy and urothelial carcinoma has yet to be characterized. The major components of aristolochic acid are metabolized to mutagenic compounds called *aristolactam I* and *aristolactam II*, respectively, which form aristolochic acid–DNA adducts in humans. These adducts cause direct DNA damage and may lead to proximal tubular atrophy and apoptosis.[119]

Prevention

The primary means of preventing aristolochic acid nephropathy is the limitation of exposure to compounds containing aristolochic acids. Several countries, including the United States, the United Kingdom, Canada, Australia, and Germany, have banned the use of herbs containing *Aristolochia*.[119] In patients that develop aristolochic acid nephropathy, treatment with corticosteroids along with toxin elimination have beneficial results.

Papillary Necrosis

Papillary necrosis is a form of chronic tubulointerstitial nephritis characterized by necrosis of the renal papillae, the regions of the kidney where the collecting ducts enter the renal pelvis, which leads to progressive kidney disease. Papillary necrosis is associated with diabetes, sickle cell disease, obstruction and infection of the urinary tract, and most commonly analgesic use.[120]

Analgesic Nephropathy

Incidence

Prototypical analgesic nephropathy is characterized by chronic tubulointerstitial nephritis with papillary necrosis.[120] Chronic excessive consumption of combination analgesics, particularly those containing phenacetin, was believed to be the major cause and led to the removal of phenacetin and phenacetin mixtures from most world markets. However, contemporary analgesics, particularly aspirin, acetaminophen, and NSAIDs, alone or in combination, are also associated with the development of analgesic nephropathy. The incidence of analgesic nephropathy has declined significantly since removal of phenacetin from many countries, with the prevalence now less than 5% in the US-adult ESKD population.[120]

Clinical Presentation

Analgesic nephropathy is a progressive disease that evolves slowly over several years.[120] It is difficult to recognize in the early stages of the disease because patients are often asymptomatic, and it may be underdiagnosed as a cause of ESKD. It is seen more commonly in women than men. Early manifestations are generally nonspecific and may include headache and upper GI symptoms; later manifestations include impaired urinary concentrating ability, dysuria, sterile pyuria, microscopic hematuria, mild proteinuria (less than 1.5 g/day), and lower back pain. As disease progresses, hypertension, atherosclerotic cardiovascular disease, renal calculi, and bladder stones are common, and pyelonephritis is a classic finding in advanced analgesic nephropathy. The most sensitive and specific diagnostic criteria include: (a) a history of chronic daily habitual analgesic ingestion (daily use for at least 3 to 5 years); (b) IV pyelography, renal ultrasound, or renal computed tomography imaging, which reveals decreased renal mass and bumpy renal contours; (c) elevated S_{cr}, that is, up to 4 mg/dL (354 µmol/L); and (d) papillary calcifications.[120]

Pathogenesis

Analgesic nephropathy originates in the papillary tip as a result of accumulated toxins, drugs and metabolites, decreased blood flow, and impaired cellular energy production. The metabolism of phenacetin to acetaminophen, which is then oxidized to toxic-free radicals that are concentrated in the papilla, is the initiating factor that causes toxicity by mechanisms analogous to acetaminophen hepatotoxicity via glutathione depletion.[121] Cortical interstitial nephritis develops secondary to papillary necrosis. Salicylates potentiate these effects by also depleting renal glutathione, and inhibiting prostaglandin-mediated vasodilation, thus further predisposing the renal medulla to ischemic injury.[121]

Risk Factors

The epidemiology of analgesic use and analgesic nephropathy continues to evolve. The classic concept persists that risk for ESKD increases with cumulative consumption of combination analgesics, phenacetin, or acetaminophen and aspirin or NSAIDs. Caffeine contained in combination analgesics may increase risk, but the role is not clear.[120] Chronic use of therapeutic doses of NSAIDs or high-dose acetaminophen, but not aspirin or salicylates alone, can cause analgesic nephropathy.

Prevention

Prevention has depended primarily on public health efforts to restrict the sale of phenacetin and combination analgesics. However, risk continues with ongoing availability of nonprescription combination analgesics containing aspirin, acetaminophen, and caffeine in the United States and throughout the world.

Individuals requiring chronic analgesic therapy may reduce risk by limiting the total dose, avoiding combined use of two or more analgesics, and maintaining good hydration to prevent renal ischemia and decrease the papillary concentration of toxic substances. Acetaminophen remains the preferred nonopiate analgesic for patients with preexisting kidney disease.

Management

Treatment of established nephrotoxicity requires cessation of analgesic consumption.[121] This can prevent progression and may improve kidney function. Kidney function indices, including urine output, BUN, and S_{cr}, should be monitored every several months. Patients should also be monitored for the development of transitional cell carcinoma of the renal pelvis, calyces, ureters, and bladder, which may present years after analgesic nephropathy is diagnosed.

RENAL VASCULITIS, THROMBOSIS, AND CHOLESTEROL EMBOLI

Renal Vasculitis

Drug-induced renal vascular disease commonly presents as vasculitis, thrombotic microangiopathy, or cholesterol emboli.[104,122] Vasculitis implies inflammation of the vessel wall, capillaries, or glomeruli and is typically classified according to vessel size (ie, small, medium, or large vessel vasculitis). Small vessel vasculitides usually affect multiple organ systems, including the kidneys and lungs, and are associated with nonspecific inflammatory symptoms such as fever, malaise, myalgias, arthralgias, and weight loss. Numerous drugs are associated with the development of renal vasculitis, including hydralazine, propylthiouracil, allopurinol, phenytoin, sulfasalazine, penicillamine, and minocycline (see Table 65-1).[104,122] Most drug-induced cases of vasculitis, including hydralazine, propylthiouracil, allopurinol, penicillamine, and the anti-TNF-α drug adalimumab, have been implicated in the development of antineutrophil cytoplasmic antibody–positive vasculitis.[104,122,123] Patients present with hematuria, proteinuria, oliguria, and red cell casts, frequently along with fever, malaise, myalgias, and arthralgias.[122] Treatment typically consists of withdrawing the offending drug and administration of corticosteroids or other immunosuppressive therapy, and usually leads to resolution of symptoms within weeks to months.

Thrombotic Microangiopathy

Thrombotic microangiopathy is characterized clinically by microangiopathic hemolytic anemia, fragmented red cells, and thrombocytopenia and pathologically by vascular endothelial proliferation, endothelial cell swelling, and intraluminal platelet thrombi in the small vessels, particularly affecting the renal and cerebral capillaries and arterioles.[103,124] The absence of inflammation in vessel walls distinguishes thrombotic microangiopathy from vasculitis. Numerous medications, including oral contraceptive agents, cyclosporine, tacrolimus, muromonab-CD3, many cancer chemotherapeutic agents including antiangiogenesis drugs (eg, bevacizumab, sunitinib, and sorafenib), mitomycin C, cisplatin, and gemcitabine, interferon-α, ticlopidine, clopidogrel, quinine, and several antimicrobial agents (eg, valacyclovir, penicillins, rifampin, and metronidazole) are associated with the development of thrombotic microangiopathy.[103,124] Patients may present with fever, neurological dysfunction, elevated S_{cr} and BUN, and hypertension, along with microangiopathic hemolytic anemia and thrombocytopenia. Kidney injury can be severe and irreversible, although corticosteroids, antiplatelet agents, plasma exchange, plasmapheresis, and high-dose IV immunoglobulin G have each induced clinical improvement.[124]

Cholesterol Emboli

Anticoagulants (particularly warfarin) and thrombolytics (eg, urokinase, streptokinase, and tissue-plasminogen activator) are associated with cholesterol embolization of the kidney.[125] These drugs act to remove or prevent thrombus formation over ulcerative plaques or may induce hemorrhage within clots, thereby causing showers of cholesterol crystals that lodge in small-diameter arteries of the kidney (renal arterioles and glomerular capillaries). Cholesterol crystal emboli induce an endothelial inflammatory response, which leads to complete obstruction, ischemia, and necrosis of affected vessels within weeks to months after initiation of therapy.[125] Purple discoloration of the toes and mottled skin over the legs are important clinical clues. Treatment is supportive in nature, since kidney injury is generally irreversible.

PHARMACOECONOMICS

The pharmacoeconomic implications of DIKD are enormous. In general, an episode of AKI leads to higher hospital resource use, with increases in the median direct hospital cost of $2,600 and the hospital length of stay by 5 days.[126] An increase in S_{cr} of greater than or equal to 0.5 mg/dL (44 μmol/L) is independently associated with a 6.5-fold increase in the odds of death, a 3.5-day increase in length of hospital stay, and nearly $7,500 in excess hospital costs even after adjusting for age, sex, and measures of comorbidity.[127] Amphotericin B–induced AKI leads to a mean increased length of hospital stay of 8.2 days and adjusted additional costs of $29,823 per patient.[128] The major driver of the increased costs associated with contrast-induced AKI was the cost of the longer initial hospital stay. The increased availability of automated clinical decision support systems and computer-guided medication dosing for hospital inpatients may improve the safety of potentially harmful drugs and minimize the occurrence of nephrotoxicity in this setting, thereby potentially lowering the corresponding economic consequences.[128]

ABBREVIATIONS

ACEI	angiotensin-converting enzyme inhibitor
AIN	allergic interstitial nephritis
AKI	acute kidney injury
ARB	angiotensin II receptor blocker
ATN	acute tubular necrosis
BUN	blood urea nitrogen
CI-AKI	contrast media–induced AKI
CKD	chronic kidney disease
COX	cyclooxygenase
CRS	cytokine release syndrome
CTLA-4	cytotoxic T-lymphocyte antigen-4
DIKD	drug-induced kidney disease
ESKD	end-stage kidney disease
FAERS	FDA Adverse Event Reporting System
FDA	Food and Drug Administration
FSGS	focal segmental glomerulosclerosis
GFR	glomerular filtration rate
IGFBP7	insulin-like growth factor–binding protein 7
KIM-1	kidney injury molecule-1
NGAL	neutrophil gelatinase–associated lipocalin
NSAIDs	nonsteroidal anti-inflammatory drugs
OSPS	oral sodium phosphate solution
PD-1	programmed cell death protein-1
PPI	proton pump inhibitor
RAS	renin–angiotensin system
RTEC	renal tubular epithelial cell

S_{cr}	serum creatinine
SGLT-2	sodium-glucose co-transporter 2
TIMP-2	tissue inhibitor of metalloproteinase 2

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements regarding drug-induced kidney disease (DIKD) is CORRECT?

A. A temporal relationship between DIKD and administration of the potentially toxic agent is rarely observed.

B. The offending agent is rarely identified.

C. DIKD is characterized by a slowly developing and transient reduction in GFR.

D. The most common presentation of DIKD in the hospital setting is acute tubular necrosis.

2. Which of the following is associated with hemodynamically mediated kidney injury induced by angiotensin converting enzyme inhibitors?

A. Enhanced efferent arteriolar dilation

B. Patients with renal artery stenosis at decreased risk

C. Increase in glomerular capillary hydrostatic pressure

D. Increased glomerular ultrafiltration

3. Which of the following is the most common manifestation of drug-induced kidney disease?

A. Proteinuria

B. Pyuria

C. Hematuria

D. A decline in the glomerular filtration rate (GFR)

4. Which of the following statements regarding aminoglycoside-induced acute tubular necrosis is CORRECT?

A. Risk factors include young age.

B. Serum creatinine gradually increases 4 to 6 weeks after exposure to the drug.

C. Patients typically present with non-oliguria, maintaining urine volumes greater than 500 mL/day.

D. Toxicity of various aminoglycosides is related to anionic charge of the drug.

5. Which of the following drugs has been associated with chronic interstitial nephritis?

A. Penicillin

B. Radiographic contrast media

C. Lithium

D. Acyclovir

6. Which of the following drugs has been associated with nephrocalcinosis leading to obstructive nephropathy?

A. Propylthiouracil

B. Aminoglycosides

C. Radiographic contrast media

D. Oral sodium phosphate solution

7. Which of the following is the preferred agent for prevention of cisplatin-induced nephrotoxicity?

   A. Fenoldopam

   B. Amifostine

   C. Dopamine

   D. Acetylcysteine

8. Which of the following segments of the nephron is associated with nephrotoxicity from pamidronate therapy?

   A. Glomerulus

   B. Proximal tubule

   C. Distal tubule

   D. Collecting duct

9. Which of the following strategies is used to prevent radiographic contrast media nephrotoxicity?

   A. Amifostine

   B. Avoid concurrent use of other nephrotoxins

   C. Use of high osmolality agents

   D. Diuretic therapy

10. Which of the following drugs is associated with cholesterol embolization of the kidney?

   A. Hydralazine

   B. Allopurinol

   C. Warfarin

   D. Propylthiouracil

11. Which of the following drugs would be the most likely culprit in a patient with newly diagnosed renal intratubular obstruction?

   A. Ibuprofen

   B. Losartan

   C. Amphotericin B

   D. Acyclovir

12. Which of the following is the preferred treatment for a patient with NSAID-induced minimal change glomerular injury accompanied by interstitial nephritis and proteinuria?

   A. Amifostine

   B. Pamidronate

   C. Prednisone

D. Hydration

13. A 60-year old woman with a five-year history of NSAID use is prescribed enalapril and develops acute kidney injury. What is the most likely cause of her acute kidney injury?

    A. Hemodynamically mediated kidney injury

    B. Chronic interstitial nephritis

    C. Focal segmental glomerulosclerosis

    D. Acute allergic interstitial nephritis

14. Which of the following are signs and symptoms of methicillin-induced allergic interstitial nephritis?

    A. Urinary crystals, fever, rash

    B. Fever, eosinophilia, reduced intraglomerular pressure

    C. Fever, rash, eosinophilia, oliguria

    D. Rash, eosinophilia, pyuria, urinary crystals

15. Which of the following drugs is associated with chronic interstitial nephritis?

    A. Cyclosporine

    B. Ciprofloxacin

    C. Cisplatin

    D. Captopril

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** The most common presentation of DIKD in the hospital setting is acute tubular necrosis, characterized by an abrupt reduction in GFR. A temporal relationship between DIKD and administration of the potentially toxic agent is typically observed, and the offending agent is usually identified.

2. **A.** Angiotensin converting enzyme inhibitor therapy leads to a reduction in synthesis of angiotensin II, thereby preferentially dilating the efferent arteriole. This decreases outflow resistance from the glomerulus and decreases glomerular capillary hydrostatic pressure, which decreases intraglomerular pressure, glomerular ultrafiltration and GFR. Patients with renal artery stenosis are at increased risk.

3. **D.** The most common manifestation of drug-induced kidney disease, regardless of etiology, is a decline in the glomerular filtration rate. See the "Clinical Presentation" for more information.

4. **C.** Clinical evidence of aminoglycoside-induced nephrotoxicity is typically seen within five to seven days after initiation of therapy and manifests as a gradual progressive rise in Scr and BUN and decrease in creatinine clearance. Patients usually present with non-oliguria. Risk factors include increased age. The number of cationic groups on the drug molecule correlates with the degree of nephrotoxicity.

5. **C.** Lithium is associated with chronic interstitial nephritis. Penicillin is associated with acute allergic interstitial nephritis. Contrast media causes acute tubular injury, while acyclovir therapy is associated with obstructive nephropathy.

6. **D.** Oral sodium phosphate solution is associated with nephrocalcinosis. Aminoglycosides and contrast media cause acute tubular injury, and propylthiouracil may cause renal vasculitis.

7. **B.** Amifostine chelates cisplatin in normal cells and reduces nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression. It serves as a thiol

donor, thereby reducing intracellular reactive oxygen species and corresponding oxidative stress that plays a critical role in the development of cellular injury. See the "Cisplatin Nephrotoxicity" section for more information.

8. **A.** Pamidronate therapy is associated with two types of glomerular disease, minimal change disease and focal segmental glomerulosclerosis. See the "Glomerular Disease" section for more information.

9. **B.** It is critically important to avoid concurrent use of potentially nephrotoxic drugs (eg, NSAIDs, aminoglycosides) during administration and use of contrast media. Other strategies include use of low- or iso-osmolar contrast agents and hydration with isotonic sodium chloride.

10. **C.** Anticoagulants (particularly warfarin) and thrombolytics are associated with cholesterol embolization of the kidney. These drugs act to remove or prevent thrombus formation over ulcerative plaques or may induce hemorrhage within clots, thereby causing showers of cholesterol crystals that lodge in small-diameter arteries of the kidney.

11. **D.** Acyclovir is relatively insoluble at physiologic urine pH and is associated with intratubular precipitation and obstruction, particularly in dehydrated oliguric patients.

12. **C.** Proteinuria usually resolves rapidly after discontinuation of the offending drug and a course of corticosteroids (eg, prednisone), which is the preferred treatment. Amifostine is used to reduce the toxicities associated with cisplatin and carboplatin therapy, while hydration is commonly used for prevention of acute tubular necrosis associated with agents such as aminoglycosides, contrast media, and cisplatin.

13. **A.** When ACE inhibitor therapy (eg, enalapril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases intraglomerular pressure and GFR. This in turn often leads to hemodynamically mediated kidney injury, particularly in the setting of reduced renal blood flow or concurrent NSAID use. See the "Hemodynamically Mediated Kidney Injury" section for more information.

14. **C.** Clinical signs present approximately 14 days after initiation of the offending drug and commonly include (with their approximate incidence) fever (27%-80%), maculopapular rash (15%-25%), eosinophilia (23%-80%), arthralgia (45%), and oliguria (50%).

15. **A.** Cyclosporine use is associated with development of chronic interstitial nephritis. Ciprofloxacin, cisplatin, and captopril are associated with acute allergic interstitial nephritis, acute tubular injury, and hemodynamically mediated kidney injury.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 67: Personalized Pharmacotherapy for Patients with Chronic Kidney Disease

Morgan A. Butrovich; Thomas D. Nolin

KEY CONCEPTS

KEY CONCEPTS

① Chronic kidney disease (CKD) and related comorbidities can impact processes contributing to medication absorption and bioavailability, but the significance of these changes is ill-defined for most medications.

② The volume of distribution (V_D) of many medications is increased in the presence of acute kidney injury (AKI) and CKD secondary to volume expansion and/or decreased protein binding.

③ Renal clearance (CL_R) is a composite of renal excretory functions (filtration, secretion, and reabsorption) and their decline in the setting of CKD, causing accumulation of medications that are predominantly renally excreted.

④ Nonrenal clearance (CL_{NR}) may be altered in CKD, causing accumulation of medications that are predominantly cleared by metabolism and/or transport.

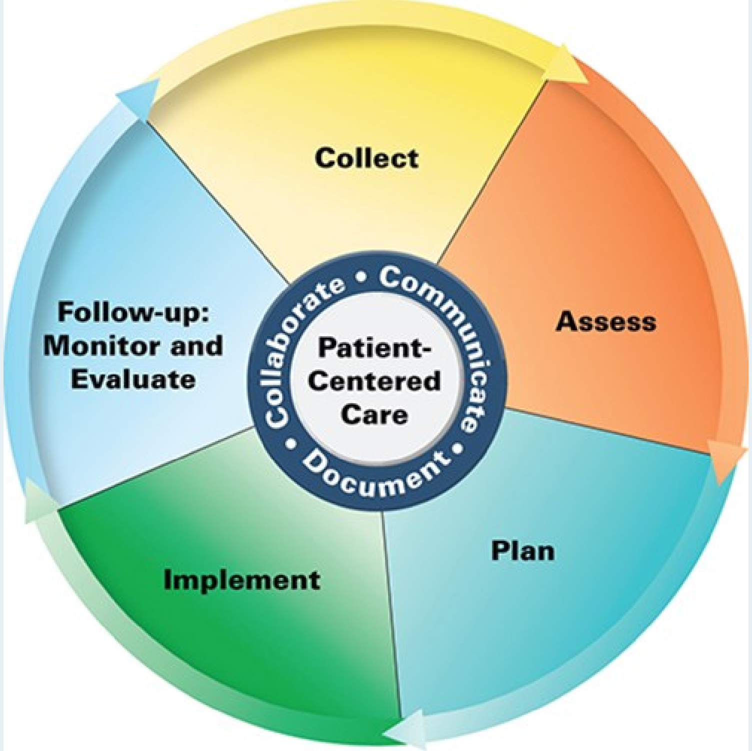
⑤ Although information on pharmacokinetics and medication dosing in patients with impaired kidney function has improved in recent years, dosing guidelines remain highly variable and many are not optimal for clinical use.

⑥ Individualization of a medication dosage regimen for a patient with impaired kidney function is based on the pharmacodynamic/pharmacokinetic characteristics of the medication, the patient's degree of residual kidney function, and the patient's overall clinical condition.

⑦ The effect of dialysis on medication elimination is dependent on the characteristics of the medication and the dialysis prescription. Hemodialysis (HD) clearance data can be used to guide the initial medication dosage regimen recommendation; however, prospective monitoring of serum concentrations is often warranted, especially for narrow therapeutic index drugs.

PATIENT CARE PROCESS

Patient Care Process for Personalizing Pharmacotherapy in Patients with Chronic Kidney Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, height, weight)
- Patient medical history (personal and family)
- Social history (eg, use of tobacco, alcohol, other substances of misuse)
- Current medications including over-the-counter products, and herbal/dietary supplements
- Objective data
    - Labs including serum creatinine and/or cystatin C

Assess

- Kidney function
    - Estimated GFR or CL_{Cr} for medication dosing based on best available methodology (see Chapter e60)
    - Measured CL_{Cr} or GFR as confirmatory test as needed
- Medication regimen
    - Indication and treatment goals for all medications
    - Potential drug-drug interactions
    - Identify medications requiring adjustment to the dosage regimen (see Table 67-3)

Plan*

- Adjusted dosage regimen as needed for each medication
    - Calculate adjusted regimen (dose and frequency) based on pharmacokinetic characteristics and patient's kidney function (see Tables 67-4 and 67-5)
- Treatment goals and corresponding monitoring parameters

Implement[*]

- Provide patient education regarding all elements of treatment plan
- Discontinue or avoid prescription of nephrotoxic medication if possible

Follow-up: Monitor and Evaluate

- Medication serum concentrations if therapeutic drug monitoring is available/applicable
- Parameters of medication response and toxicity (adverse medication reactions)
- Kidney function every 3 to 5 days for acute therapies and monthly or quarterly for chronic medications
- Revise regimen based on medication response or change in patient status (including change in kidney function)
- Patient adherence to treatment plan using multiple sources of information

[*] *Collaborate with patient, caregivers, and other health professionals.*

BEYOND THE BOOK

Visit the US National Library of Medicine website DailyMed https://dailymed.nlm.nih.gov/dailymed/index.cfm, which is the official provider of US Food and Drug Administration (FDA) approved medication label information (ie, package inserts). Identify two medications, one that is predominantly renally excreted [$f_e > 0.3$] and one that is not [$f_e < 0.3$]), and that require dose adjustment for impaired kidney function. Review the renal dosing adjustment recommendations and develop a table that compares and contrasts the kidney function cutoffs for dose adjustment, the kidney function estimate (eg, creatinine clearance, glomerular filtration rate) upon which the recommendations are based, and the dosage regimen adjustment strategy used (ie, decrease dose or increase dosing interval). This activity is useful to enhance student understanding of the ASSESS and PLAN steps in the patient care process.

INTRODUCTION

Chronic kidney disease (CKD) is defined by the presence of abnormalities of kidney function or structure for more than 3 months (see Chapter e60, "Evaluation of Kidney Function" and Chapter 62, "Chronic Kidney Disease").[1] The Kidney Disease: Improving Global Outcomes (KDIGO) CKD categories by GFR cutoff are depicted in Fig. 62-1. About 10% to 15% of the global population and 1 in 7 US adults have CKD.[2–5] CKD patients are characterized by a high prevalence of polypharmacy, with a median of eight prescribed medications per patient and up to 90% of CKD patients taking over five medications daily.[6,7] Therefore, understanding the changes in pharmacokinetics, pharmacodynamics, and medication dosing in this patient population is crucial for personalizing pharmacotherapy and optimizing pharmacotherapeutic outcomes.

CKD patients exhibit altered pharmacokinetics and/or pharmacodynamics due to disease-related physiologic and biochemical changes, including altered renal excretory function, protein binding, and cytochrome P450 enzyme and/or transporter activity.[8–15] Changes to medication absorption and bioavailability are not well quantified, while changes to distribution and elimination are better described. Medications with a high fraction excreted unchanged in the urine ($f_e > 0.3$) may accumulate in CKD patients due to a decline in the renal excretory functions (filtration, secretion, and reabsorption) that compose renal clearance (CL_R). Medications that are not predominantly renally eliminated (ie, are predominantly eliminated by metabolism and/or transport) may also accumulate in patients with CKD secondary to CKD-associated changes in nonrenal clearance (CL_{NR}).

In CKD patients, the dosage regimens of numerous medications must be altered to prevent toxicity without compromising the desired therapeutic benefit.[11,16] An accurate assessment of patient kidney function is a crucial first step in renal dose adjustment. Despite conduction of more renal impairment studies by industry and improvements in product labeling language, challenges remain for dose adjustments of medications in CKD patients.[17] If there is no official dosage regimen recommendation in the product labeling, an adjustment may be calculated on the basis of the medication's f_e and the patient's residual kidney function.[18] For medications that are extensively metabolized or for which dramatic changes in protein binding and/or volume of distribution (V_D) have been noted, a complex adjustment strategy may need to be employed.[19,20] For patients receiving chronic renal replacement therapy (ie, dialysis), medication dosage adjustments will be based on characteristics of the drug, the dialysis prescription, and the clinical setting for which dialysis is being performed, and prospective monitoring of serum drug concentrations may be warranted.[19]

Clinicians will often need to design individualized therapeutic regimens to optimize clinical outcomes in patients with kidney impairment.[11] In this chapter, the influence of CKD on pharmacokinetics and pharmacodynamics is examined. A general approach to personalizing pharmacotherapy with emphasis on medication selection and dosing strategies for CKD patients is presented. Finally, the impact of chronic renal replacement therapy on drug disposition is discussed. Medication dosage adjustment strategies for patients with acute kidney injury (AKI), including those who are receiving continuous renal replacement therapy, are presented in Chapter 61, "Acute Kidney Injury".

PHARMACOKINETIC AND PHARMACODYNAMIC CHANGES IN CHRONIC KIDNEY DISEASE

The pharmacokinetics and pharmacodynamics of numerous medications are altered by CKD.[8–14] An understanding of why and how pharmacokinetic processes are impacted by CKD provides a framework to project the influence of CKD on emerging therapies. In addition, these effects can be factored into the clinician's dosage recommendations for individual CKD patients.

Absorption and Bioavailability

① Bioavailability describes the fraction of medication reaching systemic circulation following extravascular administration. Oral bioavailability is dependent on absorption from the gastrointestinal (GI) tract and pre-systemic (ie, intestinal and hepatic) metabolism and transport. There is relatively little quantitative information regarding the influence of CKD on medication absorption and bioavailability. Most evaluations of medication absorption in CKD assess changes to peak medication serum concentration (C_{max}) and the time at which the peak serum concentration is achieved (t_{max}) rather than oral bioavailability (ie, a comparison of the area under the concentration-time curve [AUC] after oral and intravenous [IV] administration). Changes to absorption processes are likely the result of complex interplay between disease-related physiologic changes and drug-drug interactions.[8–15,21]

Altered absorption and/or bioavailability of medications in CKD patients may be a consequence of changes to GI physiologic and biochemical processes secondary to CKD and related comorbidities. These changes include decreased gastric mobility, decreased gastric acidity, GI edema, and altered pre-systemic metabolism and/or transport.[8–15,21] Decreased GI motility can occur in CKD patients secondary to diabetic gastroparesis and may delay t_{max} and decrease C_{max}, thereby altering a medication's absorption profile without impacting its bioavailability. Gastric acidity may decrease (ie, an increase in gastric pH) in CKD patients due to urea retention and subsequent conversion to ammonia by gastric urease. This alkalization may alter the dissolution or ionization properties of weakly basic drugs and lead to changes in absorption. Edema of the GI tract secondary to concomitant cirrhosis or congestive heart failure can also decrease the absorption of some medications, such as furosemide. Finally, the bioavailability of some medications (eg, dihydrocodeine, felodipine, sertraline, and cyclosporine) may be increased in CKD patients due to alterations in pre-systemic (ie, intestinal and hepatic) metabolism and/or transport that increases the amount of parent drug reaching systemic circulation (ie, decreased metabolism, increased uptake, and/or decreased efflux, see Nonrenal Clearance below).

Drug interactions can also alter the absorption and/or bioavailability of other medications through a variety of mechanisms.[8] Although not disease-specific effects, these drug-drug interactions are worth noting due to the high medication burden of CKD patients.[6,7] Administration of antacids, H_2-receptor antagonists, proton pump inhibitors, and phosphate binders can decrease gastric acidity and lower the bioavailability of several medications, such as some antibiotics and digoxin. Antacids and vitamin supplements can form insoluble salts or metal ion chelates with some medications and decrease their bioavailability. Finally, drug interactions that modulate pre-systemic intestinal and hepatic metabolism and/or transport may alter bioavailability.

Distribution

A medication's volume of distribution (V_D) reflects the extent of distribution throughout the body.[8,10] Lower V_D values reflect distribution primarily in the vascular space, whereas higher V_D values reflect extensive distribution outside the vascular space (ie, in the tissues). ② The V_D of numerous medications is increased in CKD and AKI patients as a result of fluid overload, altered protein binding, or altered tissue binding, leading to a decrease in serum drug concentrations. The V_D of a few medications may be decreased in the setting of CKD, likely due to decreased tissue binding (Table 67-1).[8,10,12–14]

TABLE 67-1

Volume of Distribution of Selected Medications in Patients with ESKD

Medication	Normal (L/kg)	ESKD (L/kg)	Change from Normal
Increased			
Amikacin	0.20	0.29	45%
Cefazolin	0.13	0.17	31%
Cefoxitin	0.16	0.26	63%
Ceftriaxone	0.28	0.48	71%
Cefuroxime	0.20	0.26	30%
Doripenem	0.25	0.47	88%
Dicloxacillin	0.08	0.18	125%
Erythromycin	0.57	1.09	91%
Furosemide	0.11	0.18	64%
Gentamicin	0.20	0.32	60%
Isoniazid	0.60	0.80	33%
Minoxidil	2.60	4.90	88%
Naproxen	0.12	0.17	42%
Phenytoin	0.64	1.40	119%

Trimethoprim	1.36	1.83	35%
Vancomycin	0.64	0.85	33%
Decreased			
Atenolol	1.20	0.90	25%
Chloramphenicol	0.87	0.60	31%
Ciprofloxacin	2.50	1.95	22%
Digoxin	7.30	4.00	45%
Ethambutol	3.70	1.60	57%
Methicillin	0.45	0.30	33%
Metoprolol	5.60	1.00	82%
Pindolol	2.10	1.10	48%
Propranolol	4.40	3.60	18%

ESKD, end-stage kidney disease.

Data from References 12 to 14.

Fluid Status

Variability in fluid status is a common issue in patients with AKI and severe CKD (category G4 and G5), especially those who are critically ill. Many critically ill patients receive large volumes of IV fluids for resuscitation from shock, and can subsequently develop edema, pleural effusions, or ascites. Furthermore, AKI and CKD can precipitate decreased water excretion. These factors can lead to fluid overload and, subsequently, an increase in V_D and a decrease in serum concentrations. This is especially problematic with hydrophilic medications, such as aminoglycosides and cephalosporins.[8,10,11]

Altered Plasma Protein Binding

Protein binding limits medication distribution, as only unbound or “free” medication can cross cellular membranes and distribute outside the vascular space. Albumin is a major drug-binding plasma protein which primarily binds acidic medications and exhibits decreased plasma concentrations in CKD.[8] Protein binding of many acidic medications such as penicillins, cephalosporins, aminoglycosides, furosemide, and phenytoin is decreased in the setting of CKD secondary to hypoalbuminemia, qualitative changes in the conformation of the protein binding site, and/or competition for binding sites by other medications, metabolites, and endogenous substances.[8,12,13,15] This increases the apparent V_D. Ultimately, a new equilibrium is established as a result of increased medication elimination/distribution, such that the unbound concentrations remain comparable to those observed in patients with normal kidney function despite the fact that total concentrations are decreased. Thus, the net effect is an alteration in the relationship between total medication concentration and pharmacodynamic effect.

For example, protein binding of phenytoin (90% protein-bound, primarily to albumin) is dramatically decreased in CKD secondary to hypoalbuminemia and decreased plasma phenytoin binding affinity for albumin. These changes alter the relationship between total phenytoin concentration and desired and toxic effects.[22] The increase in unbound fraction, from values of 10% in those with normal kidney function to 20% or more in those with G5 CKD, results in increased hepatic clearance and decreased total concentrations. Thus, in patients with CKD, the therapeutic range based on total phenytoin concentration is shifted downward from normal values of 10 to 20 mg/L (μg/mL; 40-79 μmol/L) to values as low as 4 to 8 mg/L (μg/mL; 16-32 μmol/L). Since the unbound concentration therapeutic range is the same for all patients, 1 to 2 mg/L (μg/mL; 4-8 μmol/L), this measurement provides the best target for individualizing phenytoin therapy in patients with CKD. One can approximate the total phenytoin concentration that would be observed in category G5 CKD patients assuming they had normal plasma protein binding ($C_{\text{normal binding}}$). The estimated total phenytoin concentration can then be interpreted in light of the usual total therapeutic range to assess the patient's response to therapy.[22] For normal or low albumin (concentration expressed in g/dL; albumin expressed in g/L must be multiplied by 0.1 prior to using the following equation) and category G5 CKD:

$$C_{\text{normal binding}} = C_{\text{reported}}/[(0.9)(0.48)(\text{albumin}/4.40)] + 0.1$$

where $C_{\text{normal binding}}$ = total phenytoin concentration that would be observed assuming patient had normal protein binding, and C_{reported} = patient's total phenytoin concentration reported by the laboratory (represents decreased plasma protein binding).

α1-cid glycoprotein is another major drug-binding plasma protein which primarily binds basic medications and exhibits increased plasma concentrations in CKD. For most medications that bind to 1-acid glycoprotein, protein binding is unaffected by CKD. However, for some medications (eg, bepridil, disopyramide), the unbound fraction may be dramatically decreased and the V_D decreased in CKD patients, especially kidney transplant and HD patients.[8,13,19]

Altered Tissue Binding

Distribution also may be affected by altered tissue binding of medications in CKD patients; this is relatively rare and limited to few medications, such as pindolol, ethambutol, and, most notably, digoxin.[13] The V_D of digoxin is decreased by up to 50% in patients with category G5 CKD, leading to elevated serum concentrations.[23] In this case, the absolute amount of digoxin bound to the receptor is decreased and the resultant serum digoxin concentration is higher than anticipated. Thus, in CKD patients, particularly in those with category G5, a "normal" total medication concentration may be associated with either an adverse reaction secondary to elevated unbound medication concentrations, or a subtherapeutic response because of an altered plasma-to-tissue medication concentration ratio. The monitoring of unbound medication concentrations in CKD patients is thus warranted for those medications that have a narrow therapeutic range, are highly protein bound (unbound fraction of less than 20%), and for which marked variability in the unbound fraction is possible (eg, phenytoin and disopyramide).

V_D Calculation Method

Finally, determination of the influence of CKD on V_D may depend on the method used to calculate V_D. The three most commonly used volume of distribution terms are: volume of the central compartment (V_c, which relates drug concentration and amount immediately following IV bolus administration), volume of the terminal phase (V_β and V_{area}, which relates drug concentration and amount during the terminal elimination phase), and volume of distribution at steady state (V_{ss}, which relates drug concentration and amount at IV infusion steady state). For many medications, V_c approximates extracellular fluid volume and thus may be increased or decreased by acute changes in fluid status; oliguric AKI is often accompanied by fluid overload and a resultant increased V_c for many medications. V_{area} and V_β are affected by both distribution and the terminal elimination rate constant, whereas V_{ss} has the advantage of being independent of medication elimination. Therefore, V_{ss} is the most appropriate volume term to use when one desires to compare drug distribution volumes between patients with impaired kidney function and those with normal kidney function.[24]

Elimination

Elimination of medication from the body is characterized in pharmacokinetic terms as total systemic clearance (CL_T). CL_T is the sum of all organ clearances and can be defined simply as the sum of renal clearance (CL_R) and nonrenal clearance (CL_{NR}).[8,10,13] Both CL_R and CL_{NR} can be altered in the setting of CKD.

Renal Clearance

③ Kidney function is the most quantifiable determinant of medication clearance. CL_R is a composite of all renal excretory functions, namely, filtration, tubular secretion, and tubular reabsorption ($CL_R = CL_{\text{filtration}} + CL_{\text{secretion}} - CL_{\text{reabsorption}}$).[10,12,13] Filtration clearance occurs by diffusion and is a function of GFR and the fraction of the medication that is unbound to plasma proteins (f_u) and thus available to be freely filtered ($CL_{\text{filtration}} = \text{GFR} \times f_u$). Tubular secretion and reabsorption are bidirectional processes that involve carrier-mediated renal transport systems consisting of uptake and efflux transporters located on the basolateral and apical membranes of tubular cells, respectively.[13,25,26]

Renal transport systems have been broadly classified on the basis of substrate selectivity into the anionic and cationic renal transport systems, which are responsible for the transport of a number of organic acidic and basic medications, respectively.[13,25,26] Basolateral uptake of medications into renal tubular cells from the plasma is mediated primarily by organic anion transporters (OATs), organic anion transporting polypeptides (OATPs), and organic cation transporters (OCTs). Apical efflux of medications from renal tubular cells to the tubular lumen is mediated primarily by multidrug resistance proteins (MRPs), breast cancer resistance protein (BCRP), P-glycoprotein (P-gp), multidrug and toxin extrusion proteins (MATEs), and organic cation/carnitine transporters (OCTNs). Many drugs are actively secreted by one or more of these transporter families, which include organic anionic (eg, ampicillin, furosemide, and hydrochlorothiazide), organic cationic (eg, metformin, cetirizine, and cisplatin), and P-gp transporters (eg, digoxin, sitagliptin, and apixaban).[25]

Medications that are majority excreted via the renal route (ie, $f_e > 0.3$) are likely to have their pharmacokinetics altered by decreases in CL_R secondary to CKD.[17] Reduction in kidney mass, the number of functioning nephrons, renal blood flow, GFR, and/or the rate of tubular secretion and reabsorption all contribute to the decreased renal excretory capacity observed in CKD.[8] The intact nephron hypothesis describes the anatomic and physiologic changes to the nephron population in CKD and states that as CKD progresses, all facets of renal excretory function (filtration, secretion, and reabsorption) will decline in parallel.[27,28] However, CL_R of medications may violate the intact nephron hypothesis in that renal secretory function may decline more quickly or more slowly than renal filtration function.[29–31] For example, OAT1 and OAT3 substrates exhibit a greater decline in $CL_{\text{secretion}}$ than $CL_{\text{filtration}}$ in patients with severe CKD, suggesting that tubular secretion declines more quickly than glomerular filtration.[29,31] The impact of CKD on renal secretory function is dependent on the transporter systems involved in clearance and/or the medication being secreted.[30]

For medications that are primarily filtered, a decrease in GFR will result in a proportional decrease in CL_R. However, for medications that are highly secreted, a decrease in GFR may result in a variable decrease in CL_R depending on the relative decline in secretory function compared to GFR. Therefore, the impact of CKD on CL_R of a medication may depend on the renal excretory profile of the drug (ie, the relative contributions of filtration, secretion, and reabsorption to overall CL_R and the relevant transporter pathways involved in secretion and reabsorption).[30]

Nonrenal Clearance

CL_{NR} encompasses all routes of medication elimination other than renal excretion of unchanged drug, and broadly includes hepatic and extrahepatic metabolism and transcellular transport pathways. Major CL_{NR} pathways include oxidative metabolism by cytochrome P450s (CYPs), conjugative metabolism by uridine diphosphate-glucuronosyltransferases (UGTs), and transport by OATPs, MRPs, BCRP, and other transporters.[9,10,15,32] CKD, particularly end-stage kidney disease (ESKD), impacts CL_{NR} of many drugs (Table 67-2). Over 30% of medications with $f_e < 0.3$ require a renal dose adjustment.[13,14,17,33] The impact of CKD on CL_{NR} is due largely to altered activity of drug-metabolizing enzymes and transporters in the liver and other organs. It is believed that these effects are due to accumulation of solutes that would otherwise be renally cleared in CKD patients (ie, uremic solutes), which may inhibit drug-metabolizing enzymes and/or transporters by downregulation of mRNA and/or protein expression and/or by direct inhibition.[8,10,13–15]

TABLE 67-2

Impact of ESKD on CL_{NR} of Selected Medications

Medication Name	Decreased Change in CL_{NR}
Acyclovir	50%
Aztreonam	33%
Bupropion	↓
Captopril	50%
Carvedilol	↓
Cefotaxime	40%
Ceftriaxone	↓
Cimetidine	46%
Ciprofloxacin	33%
Doripenem	↓
Erythromycin	↓
Imipenem	58%
Isoniazid	↓
Ketorolac	↓
Losartan	↓
Lovastatin	↓
Metoclopramide	66%
Minoxidil	46%
Morphine	40%
Nicardipine	37%
Nimodipine	87%
Nortriptyline	↓
Procainamide	60%
Quinapril	↓
Raloxifene	↓

Repaglinide	↓
Rosuvastatin	↓
Simvastatin	↓
Valsartan	↓
Vancomycin	43%
Verapamil	54%
Warfarin	50%

CL_{NR}, nonrenal clearance; ESKD, end-stage kidney disease.

↓ a decrease is documented but not quantified.

Data from References 13, 14, and 33.

Importantly, the impact of CKD on CL_{NR} is pathway-specific; not all metabolizing enzymes and transporters are impacted by CKD or altered to the same magnitude by CKD. Drug metabolizing enzymes are only modestly affected by CKD. For example, the activities of CYP1A2, CYP2C8, CYP2C9, and CYP2C19 do not appear to be altered to a clinically significant extent in CKD. Conversely, the activity of CYP2D6 may be decreased in CKD.[34–36] The activity of CYP3A4 in CKD is of great interest, considering CYP3A4 is responsible for the metabolism of many medications on the market. Although there are conflicting clinical reports, CYP3A4 activity is generally preserved in patients with CKD.[8,10,13–15,36–38] Conversely, the activity of extrarenal transporters may often be affected by CKD. For example, there is a 40% to 60% decrease in hepatic OATP activity in patients with severe CKD.[34,35] Furthermore, the effect of CKD on CL_{NR} may depend partly on whether the decrease in kidney function is acute or chronic. For example, higher residual CL_{NR} has been documented in AKI versus CKD for patients receiving vancomycin and imipenem with comparable creatinine clearance (CL_{cr}).[11,15,39,40]

CKD-associated changes to CL_{NR} are complex and the result of pathway-specific changes to CL_{NR} and overlapping substrate specificity of medication for multiple drug-metabolizing enzymes and/or transporters. Therefore, prediction of the effect of kidney disease on the metabolism of a particular medication is difficult and there is no quantitative strategy to predict changes for one medication based on data from another, even if they are in the same pharmacologic class. However, some qualitative insight can be gained if one knows what enzyme is involved in the metabolism of the drug of interest and how the enzyme or transporter is affected by CKD.

Accumulation of Metabolites

CKD patients who are receiving chronic pharmacotherapy may experience considerable accumulation of metabolite(s) as well as the parent compound, particularly if the ultimate route of metabolite elimination is renal. Metabolites of several medications have significant pharmacologic and/or toxicologic activity. However, the pharmacokinetics and pharmacodynamics of metabolites are not often fully elucidated during the drug development process. Because of the multiplicity of potential interactions of compounds that are primarily metabolized, the practical consequences of metabolite accumulation are difficult to predict and are most often identified in patients at risk serendipitously.

The metabolite may have similar pharmacologic activity to the parent drug and thus contribute significantly to clinical and toxicologic response.[16] For example, the liver rapidly metabolizes morphine into active metabolites, morphine-3-glucuronide (M3G), and morphine-6-glucuronide (M6G), which readily cross the blood-brain barrier, bind to opiate receptors, and exert strong analgesic effects. In CKD patients, morphine is metabolized more slowly, and clearance of M3G and M6G decrease, resulting in prolonged narcosis and respiratory depression.[41] Alternatively, the metabolite may have qualitatively dissimilar pharmacologic action compared to the parent drug. For example, meperidine undergoes *N*-demethylation metabolism by various CYP450 isoforms to form normeperidine. Whereas meperidine has central nervous system depressant effects, normeperidine has stimulatory activity that may produce seizures.[42]

Pharmacodynamics

CKD affects multiple organ systems, and therefore the response to a medication may change beyond what would be predicted based on pharmacokinetic changes alone. For example, enoxaparin dosage reduction is required in category G4 and G5 CKD patients.[43,44] This is due to the accumulation of uremic solutes which results in complex disturbances of the coagulation system leading to an increase in bleeding. Therefore, it seems that dosage adjustment solely based on kidney function may not always lead to optimal anticoagulation outcomes in CKD patients.

Successful antibiotic or antiviral treatment of CKD patients requires not only consideration of pharmacokinetic profiles, but also the medications' pharmacodynamics, which links measures of systemic exposure (such as peak and trough serum concentrations, and AUC) to bacteriologic activity.[10] Most antibiotics demonstrate concentration-dependent or time-dependent bacterial killing. For concentration-dependent antibiotics, such as fluoroquinolones or aminoglycosides, a high ratio of the peak serum concentration to the minimum inhibitory concentration (MIC, the minimum concentration required to inhibit bacterial growth) has been associated with increased likelihood of clinical success. Conversely, for time-dependent antibiotics, such as cephalosporins, the percentage of the dosing interval spent above the MIC is the most important pharmacodynamic parameter to maximize clinical success. This has led to the utilization of prolonged infusions or even in some cases to continuous infusions. Thus, it is necessary to administer anti-infective medications with a time-dependent action more frequently whereas anti-infective medications with a concentration-dependent action should be administered with a higher maintenance dose and potentially a prolonged dosage interval to increase efficacy while minimizing toxicity. Therefore, both the pharmacodynamics and pharmacokinetics of medications may need to be considered when initiating antimicrobial therapy in CKD patients.

MEDICATION DOSAGE REGIMEN INDIVIDUALIZATION IN CHRONIC KIDNEY DISEASE

Determining the appropriate dose of medication for a patient with impaired kidney function is dependent on both patient- and medication-specific factors.[11,16] Obtaining a full clinical picture of the patient, including an accurate assessment of kidney function, is imperative. Furthermore, a thorough understanding of how kidney impairment impacts the pharmacokinetics of the medication being prescribed, and, if available, corresponding dose adjustment recommendations, is necessary to individualize pharmacotherapy. The patient care process for personalizing pharmacotherapy in patients with CKD involves a stepwise approach for adjusting medication dosage.

Estimation of Kidney Function for Personalizing Pharmacotherapy

Accurate assessment of kidney function is a critical step in determining appropriate medication dosing regimens, and the KDIGO guideline group recommends utilizing the most accurate method to assess kidney function for the individual patient.[16] A detailed discussion of the methodologies for assessing kidney function is presented in Chapter e60, "Evaluation of Kidney Function". The most common equations for estimating GFR include the Cockcroft-Gault (CG) equation (which calculates estimated creatinine clearance [eCL_{cr}]) and the several iterations of the Chronic Kidney Disease-Epidemiology Collaboration (CKD-EPI) equations (which calculate estimated GFR [eGFR]).[45–48] CG has been the most commonly used method to estimate kidney function for medication dosing for over 40 years; however, contemporary eGFR equations offer improved accuracy and precision over CG and are automatically reported in the clinical setting.[46,49]

There is considerable debate regarding which equation to estimate kidney function is the most appropriate to use for medication dosing. The CKD-EPI equations offer increased accuracy over CG.[46,47] However, for most medications, any renal pharmacokinetic studies were performed and dosing guidelines were developed using CG, and some argue that renal dose adjustment based on eGFR may be inappropriate.[50,51] Furthermore, the CKD-EPI equations provide eGFR indexed to body surface area (BSA) (ie, in mL/min/1.73 m^2), whereas CG calculates eCL_{cr} as an absolute value (ie, in mL/min). Therefore, reported eGFR values can differ significantly from eCL_{cr} if congruent units are not achieved by de-indexing for BSA (ie, converted to an absolute value by multiplying by patient BSA/1.73 m^2), especially for patients of extreme body size.[51,52] Potential discordance between medication dosing recommendations based on these equations is well established.[51,53–55] Average discordance rates between eGFR equations and CG vary between 10% and 40%. This illustrates that the kidney function-estimating equation used for medication selection and dosing can have important clinical consequences on pharmacotherapy.[56]

Although quantitative assessment of kidney function is a crucial consideration, the output of kidney function-estimating equations should not be the sole determinant for pharmacotherapeutic decision-making. Renal dose adjustment should be guided by clinical judgment, including an assessment of the risk-benefit ratio of the medication being prescribed, a complete clinical picture of the patient, and a thorough understanding of the limitations and implications of the various kidney function-estimating equations.[51] The ultimate goal of kidney function assessment and renal dose adjustment of medications is optimized and personalized pharmacotherapy.

Medication Dosing Information Resources

(5) The 1998 FDA guidance on Pharmacokinetics in Patients with Impaired Renal Function were the first official guidelines addressing when and how to conduct pharmacokinetic and pharmacodynamic studies of a new medication in patients with impaired kidney function.[57] The 1998 guidance recommended that renal pharmacokinetic studies be conducted for medications with a narrow therapeutic index, medications that are primarily renally excreted, and medications for which the parent drug or active metabolite has high hepatic clearance and significant plasma protein binding. Furthermore, the guidance recommended assessing kidney function using CL_{cr} or serum creatinine (SCr) values.[57] The most recent 2020 draft guidance expands the recommendations of when to conduct renal pharmacokinetic studies to include medications that are predominantly cleared by nonrenal routes. Additionally, the use of eGFR, as calculated by a contemporary GFR-estimating equation, is preferred to assess kidney function.[58] The adoption of the FDA guidance has resulted in increased frequency of renal pharmacokinetic studies and improved availability of renal dosing recommendations, especially for medications with predominantly renal elimination. However, a lack of renal pharmacokinetic and dosing data persists for many medications, including oncology and antiviral agents and medications with $f_e < 0.3$, for which only 56% to 66% of medications approved from 1999 to 2010 have renal pharmacokinetic studies.[17]

The KDIGO guideline group recommends adjusting the dosage of medications in patients with kidney impairment according to FDA- or EMA-approved labeling when such information is available. When this information is not available, the use of peer-reviewed literature is recommended to guide medication dosage adjustment.[16] These resources, along with other commonly used drug information sources such as Drug Prescribing in Renal Failure,[59] The Renal Drug Handbook,[60] Lexicomp,[61] Micromedex,[62] and the American Hospital Formulary Service Drug Information[63] are excellent sources of information about a medication's pharmacokinetic characteristics. However, they are not without limitation and can yield marked variation in recommendations and the paucity of details of the methods used to generate the dosing advice (Table 67-3).[64,65] In addition, none of these sources consistently provide the explicit relationships of the pharmacokinetic parameters of interest (CL_T, elimination rate constant [k], and V_D) with a continuous index of kidney function (eCL_{cr} or eGFR). To find this information, one may need to identify the primary research study that assessed the medication's disposition, which can be a time-consuming process and difficult to carry out for each medication and patient combination in real time.

TABLE 67-3

Comparison of Secondary References Used for Medication Dosing in Patients with Impaired Kidney Function

Resource	Pros	Cons
Aronoff's Drug Prescribing in Renal Failure[63]	• Exclusive focus on medication dosing in patients with impaired kidney function • Information provided for IHD, PD, CRRT • Tables include medication PK and dosage adjustment based on CL_{cr} (>50, 10-50, <10 mL/min [>0.83, 0.17-0.83, <0.17 mL/s]) • Tables for both adult and pediatric dosing provided • Concise, easy to use • References to primary literature provided	• Updated infrequently; information may not be current, newer medications may not be included • Some dosage recommendations are not feasible for dialysis patients (ie, q 36 hours dosing interval)
The Renal Drug Handbook[64]	• Easy to access with a subscription • Contains information on clinical use of medications, PK, dose in normal kidney function, dose adjustment in CKD, drug interactions and administration • Specific to CKD patients	• Updated every few years; information may not be current, newer medications may not be included • References not provided
Lexicomp[65]	• Easy to access with a subscription • Easy to navigate • Concise information • Dose adjustment in CKD provided (HD and PD)	• May be difficult to navigate • No specific focus on CKD patients • References to primary literature for dosing not provided
Micromedex[66]	• Easy to access with a subscription • Comprehensive, detailed information (both "in-depth" and "quick") • Dose adjustment in CKD provided (both HD and PD)	• May be difficult to navigate • No specific focus on CKD patients • References to primary literature for dosing not consistently provided
American Hospital Formulary Service (AHFS)[67]	• Easy to access with a subscription • Detailed medication monographs • "Dosage in Renal and Hepatic Impairment/Special Populations" section for each medication listed • Online version updated regularly, print version updated yearly	• Hard copy version can be difficult to navigate, cumbersome • Information on dose adjustment in CKD is minimal • No specific focus on CKD patients • References to primary literature for dosing not provided

MEDICATION DOSAGE REGIMENS FOR NONDIALYSIS CKD PATIENTS

⑥ Dosage regimen design in CKD patients is dependent on the pharmacodynamic/pharmacokinetic characteristics of the medication, the patient's degree of residual kidney function, and their overall clinical condition. The initial or "loading" dose for CKD patients should be the same as the dose recommended for those with normal kidney function unless the medication's V_D is known to be altered in CKD or a concomitant disease.[11] If V_D is increased, then the dose should be increased proportionally (see Table 67-1). Rapid achievement of therapeutic drug concentrations is important in many patient care situations and thus it is often better to start therapy aggressively rather than conservatively.

If available, maintenance dosage regimen guidelines for CKD patients in FDA- or EMA-approved product labeling should be the foundation for ongoing therapy.[16] Approved product labeling typically includes dose adjustment recommendations for ranges of kidney function. These ranges represent mild (eCL_{Cr} 60-90 mL/min or eGFR 60-90 mL/min/1.73 m^2), moderate (eCL_{Cr} 30-59 mL/min or eGFR 30-59 mL/min/1.73 m^2), and severe (eCL_{Cr} < 30 mL/min or eGFR <30 mL/min/1.73 m^2) kidney impairment (see Chapter 62, "Chronic Kidney Disease").[66] Each of these categories encompasses a broad range in kidney function, and thus the recommended dosage regimen may not be optimal for all patients whose kidney function lies within a given kidney function category.

Quantifying the Relationship Between Kidney Function and Medication Clearance

If FDA- or EMA-approved product labeling information is not available or if there is marked variance between these two agencies' recommendations, a stepwise approach for designing a dosage regimen for a patient with impaired kidney function can be used. In either case, the design of the optimal dosage regimen is dependent on the availability of an accurate characterization of the relationship between the pharmacokinetic parameters of the medication and kidney function and an accurate assessment of the patient's kidney function.

The "Dettli Method" is a graphical means to generate medication dosing recommendations based on the linear relationship between the elimination rate constant of a renally cleared medication and a patient's creatinine clearance:

$$k = k_{\mathrm{NR}} + (\alpha \times \mathrm{CL_{cr}})$$

k=kNR+(α×CLcr)

where k is the elimination rate constant of the medication based on a first-order one-compartment model, k_{NR} is the nonrenal elimination rate constant, and α is a constant relating the renal drug elimination rate constant to the patient's creatinine clearance (CL_{cr}).[67] This approach assumes that the overall elimination rate constant (k), relating to CL_T, declines linearly with CL_{cr}, and that the nonrenal elimination rate constant (k_{NR}), relating to CL_{NR}, remains constant as kidney function declines. While the first assumption generally holds true for medications that are mainly renally cleared, the second assumption is flawed, as CL_{NR} can be altered in CKD.[8–15] The relationship between CL_T and CL_{cr} for selected medications is depicted in Table 67-4. This information, along with the patient's eCL_{cr} or eGFR, is the foundation upon which a therapeutic regimen to attain the desired medication concentration-time profile and ultimately the therapeutic outcome can be formulated when renal dosing information is not provided in the approved product labeling information.

TABLE 67-4

Relationship Between CL_{cr} and CL_T of Selected Medications

Medication	**Total Systemic Clearance**[a]
Acyclovir	$CL_T = 3.37\ (CL_{cr}) + 0.41$
Amikacin	$CL_T = 0.6\ (CL_{cr}) + 9.6$
Aztreonam	$CL_T = 0.8\ (CL_{cr}) + 26.6$
Cefazolin	$CL_T = 0.34\ (CL_{cr}) + 6.6$
Ceftazidime	$CL_T = 1.15\ (CL_{cr}) + 10.6$
Ciprofloxacin	$CL_T = 2.83\ (CL_{cr}) + 363$
Digoxin	$CL_T = 0.88\ (CL_{cr}) + 23$
Ganciclovir	$CL_T = 1.24\ (CL_{cr}) + 8.57$
Gentamicin	$CL_T = 0.983\ (CL_{cr})$
Imipenem	$CL_T = 1.42\ (CL_{cr}) + 54$
Lithium	$CL_T = 0.20\ (CL_{cr})$
Ofloxacin	$CL_T = 1.04\ (CL_{cr}) + 38.7$
Piperacillin	$CL_T = 1.36\ (CL_{cr}) + 1.50$
Tobramycin	$CL_T = 0.801\ (CL_{cr})$
Vancomycin	$CL_T = 0.69\ (CL_{cr}) + 3.7$

CL_T, total systemic clearance; CL_{cr}, creatinine clearance.

[a] Clearance in mL/min can be converted to mL/s through multiplication by 0.0167.

However, the linear relationship of kinetic parameters to eGFR or eCL_{cr} is often not explicitly reported. In this case, then the CL_T or k for CKD patients can be estimated using the method of Rowland and Tozer, provided that f_e for subjects with normal kidney function is known.[18] This approach assumes that the change in CL_T and k are proportional to eCL_{cr}, the kidney disease does not alter the medication's metabolism, any metabolites that are formed are inactive and nontoxic, and the medication obeys first-order (linear) one-compartment kinetic principles. If these assumptions are true, which is rarely the case, then the dosage-adjustment factor (Q) can be calculated as:

$$Q = 1 - [f_e(1 - \mathrm{KF})]$$

$Q = 1 - [fe(1 - KF)]$

where KF is the ratio of the patient's kidney function (ie, eCL_{cr} or eGFR) to the assumed normal value of 120 mL/min. Thus, for a medication that is 85%

eliminated renally unchanged in a patient who has an eCL_{cr} of 10 mL/min, *Q* would be:

$$\begin{aligned} Q &= 1-[0.85[1-(10/120)]] \\ &= 1-[0.85(0.85(0.92))] \\ &= 1-0.78 \\ &= 0.22 \end{aligned}$$

Q=1–[0.85[1–(10/120)]]=1–[0.85(0.85(0.92))]=1–0.78=0.22

Designing Adjusted Renal Dosage Regimens

In order to determine the best method for dosage regimen adjustment, a regimen goal must be defined.[10,11] The goal may be pharmacokinetic (maintenance of a similar peak, trough, or average steady-state drug concentration) or pharmacodynamic (time above the MIC [eg, cephalosporins] or the ratio of the AUC relative to the MIC [eg, fluoroquinolones]). If there is a strong relationship between peak concentration and clinical response (eg, aminoglycosides) or toxicity (eg, phenobarbital and phenytoin), then the attainment of specific target values is critical for optimal therapeutic outcomes. If, however, no specific target values for peak or trough concentrations have been reported, then a regimen goal of attaining the same average steady-state concentration is likely to be appropriate.

The options to attain the desired average steady-state concentration profile in CKD patients are to either decrease the dose or increase the dosing interval (τ). If the dose is decreased and the dosing interval remains unchanged, then the average steady-state concentration will be unchanged but the peaks will be lower and the troughs will be higher. Conversely, if the dosing interval is increased and the dose remains unchanged, then the average steady-state, peak, and trough concentrations in the patient with impaired kidney function will be similar to those in the patient with normal kidney function (Fig. 67-1).[68] Increasing the dosing interval is the approach used most commonly to adjust dosage regimens in patients with impaired kidney function because it translates into a lower daily medication burden in these patients. Moreover, it is likely to yield cost savings as a result of a reduction in pharmacy and nursing time for preparation and administration of fewer (less frequent) doses, as well as a reduction in the corresponding supplies. Lastly, it is important to note that occasionally both the dose and dosing interval may need to be changed for pragmatic reasons (ie, to allow the administration of a clinically practical dose [500 mg vs a calculated value of 487 mg] or dosing interval [administer every 12 hours vs every 17 hours]).

FIGURE 67-1

Although the average steady-state concentrations (C_{ave}) are identical regardless of which dosage-adjustment strategy one decides to implement, the concentration-time profile will be markedly different if one changes the dose and maintains the dosing interval (τ) constant (*Scenario A*), versus changing the dosing interval and maintaining the dose constant (*Scenario B*) or changing both (*Scenario C*).

If the relationship between the pharmacokinetic parameters of the medication and kidney function are known (ie, equations are available such as those depicted in Table 67-4), then the change in dose and/or dosing interval for a patient with a given kidney function can be calculated and a dosage regimen adjustment can be designed using a stepwise approach. CL_T is calculated for a patient with normal kidney function (CL_{cr} or eGFR = 120 mL/min) and a patient with impaired kidney function based on available equations describing the quantitative relationship between CL_T and CL_{cr} or eGFR (as presented in Table 67-4). In this situation, the dosage-adjustment factor (*Q*) is calculated as the ratio of the estimated k or CL of the patient with impaired kidney function relative to a subject with normal kidney function. The *Q* is then used to determine the adjusted dose or dosing interval for a patient with impaired kidney function, as follows:

$$\begin{aligned} D_{\text{CKD}} &= D_{\text{norm}} \times Q \\ \tau_{\text{CKD}} &= \tau_{\text{norm}}/Q \end{aligned}$$

DCKD=Dnorm×QτCKD=τnorm/Q

where D_{CKD} is the adjusted dose for a patient with CKD, D_{norm} is the standard dose for a patient with normal kidney function, τ_{CKD} is the adjusted dosing interval for a patient with CKD, τ_{norm} is the standard dosing interval for a patient with normal kidney function, and *Q* is the dosage-adjustment factor. The strategy for dosing adjustment (ie, decrease the dose or increase dosing interval) is chosen and the corresponding dosing interval or dose is calculated.

An example of this process is illustrated in Table 67-5 for ciprofloxacin, a commonly used antibiotic for the treatment of infections in CKD and dialysis patients. Ciprofloxacin is a concentration-dependent antibiotic, and thus the peak concentration and AUC determine its efficacy. Therefore, extending the interval but keeping the same dose allows for peak concentrations in CKD patients similar to those seen in normal kidney function, allowing for this pharmacodynamic action to be achieved without accumulation of medication that could cause dose-dependent toxicities.

TABLE 67-5

Stepwise Approach to Calculating a Dosage Regimen Based on a Medication's Pharmacokinetic Properties and a Patient's Kidney Function

	Steps	**Calculation Examples with Ciprofloxacin**
Step 1	Calculate total systemic clearance of medication in an individual with normal kidney function (CL_{norm}); CL_{cr} = 120 mL/min	$CL_{\text{norm}} = [2.83\ (CL_{\text{cr}})] + 363$ $CL_{\text{norm}} = [2.83(120)] + 363$ $CL_{\text{norm}} = 702.6$ mL/min
Step 2	Calculate total systemic clearance of medication in a patient with impaired kidney function (CL_{CKD})	In patient with CL_{cr} = 15 mL/min $CL_{\text{CKD}} = [2.83(CL_{\text{cr}})] + 363$ $CL_{\text{CKD}} = [2.83(15)] + 363$ $CL_{\text{CKD}} = 405.5$ mL/min
Step 3	Calculate the dosage-adjustment factor (*Q*) for a patient with impaired kidney function as the ratio of the CL of the patient with impaired kidney function relative to an individual with normal kidney function	$Q = CL_{\text{CKD}}/CL_{\text{norm}}$ $Q = 702.6/405.5$ $Q = 0.58$
Step 4	Calculate the maintenance dose (D_{CKD}) or adjusted dosing interval (τ_{CKD}) in a patient with impaired kidney function; D_{norm} = normal dose; τ_{norm} = normal dosing interval	$D_{\text{norm}} = 500$ mg; $\tau_n = 12$ h $D_{\text{CKD}} = D_{\text{norm}} \times Q$ $D_{\text{CKD}} = 500\text{ mg} \times 0.58$ $D_{\text{CKD}} = 290$ mg

		$\tau_{CKD} = \tau_{norm}/Q$ $\tau_{CKD} = 12/0.58$ $\tau_{CKD} = 20.7$ h
Step 5	Choose dosing adjustment: Option A. Maintain D_{norm} and use τ_{CKD} Option B. Maintain τ_{norm} and use D_{CKD}	Dosing adjustments: Option A. 500 mg every 21 hr Option B. 290 mg every 12 hr
Step 6	Determine *adjusted dosing regimen* based on Option A using a practical dosing interval	D_{norm} = 500 mg; τ_{CKD} = 21 h *Practical* τ = 24 h (selected to limit missed doses)
Step 7	Recommend dosing regimen (dependent on product availability and limited risk of missed doses)	500 mg every 24 h

CL_{cr}, creatinine clearance.

Creatinine clearance in mL/min can be converted to mL/s through multiplication by 0.0167. Clearance in mL/min/1.73 m^2 can be converted to mL/s/m^2 through multiplication by 0.00963.

If the V_D of a medication is significantly altered in CKD patients or if one desires to attain a specific maximum or minimum concentration, the estimation of a dosage regimen becomes more complex. If the relationship between V_D and CL_{cr} has been characterized, then V_D may be estimated. If one assumes that a one-compartment linear model can describe the medication, the predicted V_D may then be used with the predicted *k* of the medication to yield an adjusted-dosing interval and IV dose:

$$\begin{aligned}\tau_{CKD} &= (-1/k)[\ln(C_{min}/C_{max})]\\ D_{CKD} &= V_D \times (C_{max} - C_{min})\end{aligned}$$

τCKD=(−1/k)[ln (Cmin/Cmax)]DCKD=VD × (Cmax − Cmin)

where τ_{CKD} is the adjusted dosing interval for a patient with impaired kidney function, and D_{CKD} is the adjusted dose for a patient with impaired kidney function. These principles have been used to derive dosage recommendations for many commonly used medications for CKD patients. It should be noted, however, that in most dosing guidelines, the "usual" dose or dose for "normal kidney function" represents eGFR greater than 50 mL/min/1.73 m^2. This assumption, however, could lead to dosing errors for patients with eGFRs of 60 mL/min/1.73 m^2 versus 90 mL/min/1.73 m^2 versus 130 mL/min/1.73 m^2. Augmented renal clearance, defined as CL_{cr} greater than 130 mL/min/1.73 m^2, has been associated with subtherapeutic antibiotic concentrations and outcomes in critically ill patients when standard doses of antibiotics were administered.[69] Clinicians should be aware of the potential to underdose critically ill patients with documented augmented kidney function and thus should consider the use of higher doses, especially for antibiotics and antivirals.

MEDICATION DOSAGE REGIMENS FOR DIALYSIS PATIENTS

The rationale and approaches for delivery of renal replacement therapy to patients with ESKD are described in Chapter 64, "Hemodialysis and Peritoneal Dialysis". This section will describe medication dosing regimens for patients on traditional HD, peritoneal dialysis, and alternative HD modalities, including short-daily hemodialysis (SDHD) and nocturnal hemodialysis (NHD). Several forms of continuous renal replacement therapy in clinical use today and corresponding approaches to individualize dosage regimens are described in Chapter 61, "Acute Kidney Injury".

Hemodialysis

Principles of Hemodialytic Clearance of Medications

⑦ The impact of HD on a patient's pharmacotherapy is dependent on several factors, including the physicochemical characteristics of the medication and the dialysis prescription. Medication-related factors that affect dialyzability include molecular weight, degree of protein binding, and V_D.[19] The permeability of a dialysis filter for medication depends on the composition of the filter and the molecular weight of the medication. The majority of dialysis filters in use in North America up until the mid-1990s were composed of cellulose, cellulose acetate, or regenerated cellulose (cuprophane) and were generally impermeable to medications with a molecular weight >1,000 Da.[16] Dialysis membranes in the 21st century ("high-flux" dialysis membranes) are predominantly composed of semisynthetic or synthetic materials (eg, polysulfone, polymethylmethacrylate, or polyacrylonitrile), have larger pore sizes, and more closely mimic the filtration characteristics of the human kidney. This allows for the passage of most solutes, including medications that have a molecular weight up to 20,000 Da, causing larger medications to be more easily removed with high flux dialyzers.[16] Some medications that are cleared in high-flux dialysis but not through conventional dialysis include vancomycin, carbamazepine, cisplatin, enoxaparin, ranitidine, valproic acid, sorafenib, and tramadol. The effect of HD on drug disposition is rarely reevaluated after it is initially reported; therefore, information for medications that were developed prior to the advent of high-flux dialysis membranes probably represents an underestimation of the impact of HD on a medication's disposition. Therapeutic drug monitoring for medications such as aminoglycosides and vancomycin should also be performed to ensure adequate dosing for patients on HD. Medications that are highly protein bound (ie, $f_u < 0.10$) are not well dialyzed because both of the principal drug-binding plasma proteins, α1-acid glycoprotein and albumin, have a high molecular weight. Finally, medications that are widely distributed, with V_D greater than 2 L/kg, are poorly removed by HD.

The dialysis prescription can dramatically affect the total clearance of a medication.[95] HD can occur in a number of clinical settings, including acute management of AKI, intermittent three times a week, daily for an extended period, or some combination thereof for the management of category G5 CKD patients. The primary factors that vary between patients are the composition of the dialysis filter, the filter surface area, the blood, dialysate and ultrafiltration flow rates, and whether or not the dialysis unit reuses the dialysis filter.[16]

Overall, the impact of HD on pharmacotherapy is highly variable. One cannot assume that a certain percentage of a medication is removed with each dialysis session and an "all" or "none" approach regarding the dialyzability of a medication is insufficient information to make therapeutic decisions. Characteristics of the dialysis procedure that were utilized in the drug study, such as membrane composition and surface area and blood and dialysis flow rates, are critical parameters that should be known before one uses the published HD clearance data to prospectively design a medication dosing regimen for an HD patient.

Prospective Monitoring of Medication Concentrations

If medication concentrations can be measured in the clinical setting, the quantitative impact of HD on drug disposition can be calculated in one of the several ways.[19] The most commonly utilized means for assessing the effect of HD is to calculate the dialyzer clearance (CL_D) of the medication. The CL_D^pCLDp from blood can be calculated as:

$CL_D^p = Q_p[(A_p - V_p)/A_p]$CLDp = Qp[(Ap–Vp)/Ap]

where Q_b is the blood flow through the dialyzer and Q_p is the plasma flow, which equals Q_b (1 − hematocrit); A_p is the plasma concentration of medication entering the dialyzer, and V_p is the plasma concentration of the medication leaving the dialyzer. This clearance calculation most accurately reflects dialysis drug clearance as most medications do not extensively penetrate red blood cells or bind to formed blood elements. However, for medications that readily partition into and out of erythrocytes, this equation would likely underestimate HD clearance. Furthermore, one must keep in mind that venous plasma concentrations may be artificially high and CL_D^pCLDp will be low if plasma water is removed from the blood at a faster rate than the medication. This tends to occur when extensive ultrafiltration is performed simultaneously with diffusion during dialysis.[16,19]

The following principles may be used to generate a medication dosage regimen recommendation for HD patients, if none is available in product labeling or other sources, by using a value of CL_D.[16,19] Because clearance terms are additive, the total clearance during dialysis can be calculated as the sum of the patient's underlying residual systemic clearance stemming from the patient's remaining renal clearance and nonrenal clearance during the interdialytic period (CL_{RES}) and dialyzer clearance (CL_D):

$$\mathrm{CL_T} = \mathrm{CL_{RES}} + \mathrm{CL_D}$$

CLT = CLRES + CLD

The half-life during the period between dialysis treatments and during dialysis can then be calculated from the following relationships using an estimate of the medication's V_D (see Table 67-2):[19]

$$\begin{aligned} t_{1/2,\,\mathrm{off\ HD}} &= 0.693(V_\mathrm{D}/\mathrm{CL_{RES}}) \\ t_{1/2,\,\mathrm{on\ HD}} &= 0.693\,(V_\mathrm{D}/\mathrm{CL_{RES}} + \mathrm{CL_D}) \end{aligned}$$

t1/2, off HD=0.693(VD/CLRES)t1/2, on HD=0.693 (VD/CLRES+ CLD)

Once the key pharmacokinetic parameters have been estimated/calculated, they may be used to simulate the plasma concentration-time profile of the medication for the individual patient and then one can ascertain how much medication to administer and when. This approach to personalizing pharmacotherapy can be accomplished in a stepwise fashion assuming first-order elimination of the medication and a one-compartment model.

CLINICAL CASE EXAMPLE: Personalizing Pharmacotherapy for a Hemodialysis Patient

A 54-year-old critically ill woman with ESKD was transferred to a medical intensive care unit from the general medical unit, where she was febrile with a temperature of 39°C (102.2°F). Her weight was 64 kg (141 lb) and her height was 65 in (165 cm). She had a residual CL_{cr} of 5 mL/min (0.083 mL/s), and was receiving high-flux hemodialysis (F80 polysulfone dialyzer) for 4 hours on Mondays, Wednesdays, and Fridays. She was started on vancomycin for a methicillin-resistant *Staphylococcus aureus* (MRSA) catheter-associated bacteremia and her first dose of 1,000 mg was administered at the end of her HD treatment. The first step is to estimate this patient's pharmacokinetic parameters of vancomycin using known population data (Table 67-1) and equations (Table 67-4). The V_D in this patient can be estimated to be 54.4 L (0.85 L/kg × 64 kg). Her underlying residual systemic clearance (CL_{RES}) of vancomycin is estimated from the relationship between CL_T and kidney function (where $CL_T = [0.69 \times CL_{cr}] + 3.7$) and is 7.15 mL/min (0.12 mL/s) or 0.43 L/h. The *k* can be approximated as:

$$\begin{aligned} k &= CL_\mathrm{RES}/V_\mathrm{D} \\ &= 0.43\ \mathrm{L/h}\ /\ 54.4\ \mathrm{L} \\ &= 0.0079\ \mathrm{h^{-1}} \end{aligned}$$

k=CLRES/VD=0.43 L/h / 54.4 L=0.0079 h−1

The HD clearance of vancomycin (CL_D) is dependent on the dialyzer and a value of 120 mL/min (2 mL/s; 7.2 L/hr) is a reasonable estimate for this dialyzer.[20]

One can now predict what the plasma concentrations of vancomycin will be over the next 24 to 48 hours, assuming the infusion time for the medication (*t*′) was 1 hour. The concentration at the end of the 1-hour infusion (C_{max}) would be:

$$\begin{aligned} C_\mathrm{max} &= \frac{(Dose/t')}{\mathrm{CL}_{RES}}(1 - e^{-kt'}) \\ &= \frac{(1000\,\mathrm{mg/h})}{(0.43\,\mathrm{L/h})}(1 - e^{-(0.0079)}) \\ &= (2,325.58\,\mathrm{mg/L})(0.0078) \\ &= 18.1\,\mathrm{mg/L} \end{aligned}$$

Cmax=(Dose/t′)CLRES(1−e−kt′)=(1000 mg/h)(0.43 L/h)(1−e−(0.0079))=(2,325.58 mg/L)(0.0078)=18.1 mg/L

The plasma concentration prior to the next dialysis session (C_{bD}), which is 44 hours away can be calculated as:

$$\begin{aligned} C_\mathrm{bD} &= C_\mathrm{max} \times e^{-(\mathrm{CL_{RES}}/V_\mathrm{D}) \times t} \\ &= 18.1 \times \mathrm{e}^{-0.0079 \times 44} \\ &= 12.8\,\mathrm{mg/L} \end{aligned}$$

Cb D=Cmax × e−(CLRES/VD)×t=18.1 × e−0.0079×44=12.8 mg/L

and the concentration 4 hours later after dialysis (C_{aD}) can be calculated as:

$$\begin{aligned} C_\mathrm{aD} &= C_\mathrm{bD} \times \mathrm{e}^{-[(\mathrm{CL_{RES}} + \mathrm{CL_D} + \mathrm{CL_D}/V_\mathrm{D})] \times t} \\ &= 12.8 \times \mathrm{e}^{-[(0.43+7.2)/54.4] \times 4} \\ &= 12.8 \times \mathrm{e}^{-0.14 \times 4} \\ &= 7.3\,\mathrm{mg/L} \end{aligned}$$

Ca D=Cb D × e−[(CLRES + CLD + CLD/VD)]×t=12.8 × e−[(0.43 + 7.2)/54.4] × 4=12.8 × e−0.14 × 4=7.3 mg/L

On the basis of these data, the second dose, which should be administered after the second dialysis session, was increased in order to maintain vancomycin trough concentrations between 15 and 20 mg/L (10-14 µmol/L) for an MRSA catheter-associated bacteremia, as this is likely to attain the AUC target of 400 to 600 mg·h/L in the previous 24 hours.[70,71] The patient received a vancomycin dose of 1,500 mg 4 hours after the end of the second dialysis session. The increase or change in serum concentration (ΔC) at the end of this 1-hour infusion can thus be estimated:

$$\begin{aligned} \Delta C &= \frac{(Dose/t')}{\mathrm{CL_{RES}}}(1 - e^{-kt'}) \\ &= \frac{(1500\,mg/h)}{0.43\,L/h}(1 - e^{-((0.0079)1}) \end{aligned}$$

ΔC=(Dose/t′)CLRES(1−e−kt′)=(1500 mg/h)0.43 L/h(1−e−((0.0079)1)=(3,488.4 mg/L)(0.0078)=27.2 mg/L

$$
\begin{aligned}
&= (3,488.4\,\mathrm{mg/L})(0.0078)\\
&= 27.2\,\mathrm{mg/L}
\end{aligned}
$$

Thus, the C_{max} would be approximately 34.5 mg/L (24 µmol/L), the sum of the residual concentration from the first dose of 7.3 mg/L (5 µmol/L) and the ΔC of 27.2 mg/L (18.8 µmol/L). The plasma concentration prior to the third dialysis session (C_{bD}), which is 40 hours away can be estimated as:

$$
\begin{aligned}
C_{\mathrm{bD}} &= C_{\max} \times \mathrm{e}^{(\mathrm{CL_{RES}}/V_{\mathrm{D}})\times t}\\
&= 34.5\,\mathrm{mg/L} \times \mathrm{e}^{-0.0079\times 40}\\
&= 25.2\,\mathrm{mg/L}
\end{aligned}
$$

Cb D=Cmax × e(CLRES/VD)×t=34.5 mg/L × e−0.0079×40=25.2 mg/L

and the concentration 4 hours later after the third dialysis (C_{aD}) can be estimated as:

$$
\begin{aligned}
C_{\mathrm{aD}} &= C_{\mathrm{bD}} \times \mathrm{e}^{-[(\mathrm{CL_{RES}}+\mathrm{CL_D})/V_D]\times t}\\
&= 25.2 \times \mathrm{e}^{-[(0.43+7.2)/54.4]\times 4}\\
&= 25.2 \times \mathrm{e}^{-0.14\times 4}\\
&= 14.4\,\mathrm{mg/L}
\end{aligned}
$$

Ca D=Cb D × e−[(CLRES+CLD)/VD]×t=25.2 × e−[(0.43+7.2)/54.4]×4=25.2 × e−0.14×4=14.4 mg/L

This higher dose would be considered to have achieved concentrations that are too high since the lowest value during the majority of the dosing interval exceeded 25.2 mg/L (17.1 µmol/L). The dose required to maintain vancomycin trough concentrations between 15 and 20 mg/L (10-14 µmol/L) should be determined.

For medications with a narrow therapeutic index (eg, vancomycin, phenytoin, and gentamicin), therapeutic drug monitoring (eg, plasma concentration measurements and dialyzer clearance estimation) should be utilized to guide medication dosing.[19] The ultimate reason for measuring the plasma concentrations of antibacterial agents is to individualize the patient's dosage regimen to achieve a bacteriologic cure while preventing adverse effects and preserving residual kidney function. Vancomycin dosing is primarily based on attaining desired trough concentrations, usually between 15 and 20 mg/L (10-14 µmol/L) as this is likely to attain the AUC target of 400 to 600 mg·hr/L in the previous 24 hours.[70,71] It is common practice to administer medications post-dialysis on the premise that it is desirable to minimize the loss of medication that would result from dialyzer clearance. For example, the administration of traditional doses of tobramycin (1.5 mg/kg) or vancomycin (1,000 mg) during dialysis has been associated with markedly lower AUCs than those observed when the same dose was administered post-dialysis; consequently, higher dosage regimens are usually necessary to compensate for the additional loss of medication during the dialysis procedure. However, there are clinical scenarios when pre-dialysis or intradialytic medication administration may be optimal. Medications for pain may be given on a precise schedule and thus would be administered irrespective of the time on dialysis. Furthermore, it may be optimal to administer some medications, such as aminoglycosides[72,73] and vancomycin[74,75], during or immediately prior to the start of a dialysis treatment. For example, pre-dialysis or intradialytic aminoglycoside dosing may obtain similar peak concentrations, a prime indicator of efficacy, but lower AUC, a correlate to ototoxicity and nephrotoxicity, compared to post-dialysis dosing.[72] Performing HD immediately after dosing might also be a good option for several anticancer medications. The pre-dialysis administration of a normal dose makes sense when the patient undergoes HD 2 to 12 hours later. This strategy delivers the desired maximum plasma concentration effect while minimizing patient exposure to the toxic drug or metabolite effects.[76,77]

Peritoneal Dialysis

Peritoneal dialysis, like other dialysis modalities, has the potential to affect drug disposition; however, personalizing pharmacotherapy is often less complicated in these patients as a result of the limited clearances of medications achieved with this procedure (see Chapter 64, "Hemodialysis and Peritoneal Dialysis"). In general, HD is more effective in removing medications than peritoneal dialysis such that if a medication is not removed by HD, it is unlikely to be significantly removed by peritoneal dialysis.

Many of the factors that are important in determining medication dialyzability for other treatment modalities pertain to peritoneal dialysis as well.[78,79] Factors that influence medication dialyzability by peritoneal dialysis include drug-specific characteristics such as molecular weight, solubility, degree of ionization, protein binding, and V_{D}. The intrinsic properties of the peritoneal membrane that affect medication removal include blood flow and peritoneal membrane surface area, which is approximately equal to the body surface area. There is an inverse relationship between peritoneal clearance of medications and molecular weight, protein binding, and V_{D}. In addition, medications that are ionized at physiologic pH will diffuse across the membrane more slowly than unionized compounds.[78,79]

Peritoneal dialysis, in current practice, is often prescribed to attain a urea clearance of approximately 10 mL/min (0.17 mL/s), so it is unlikely to significantly impact the CL of any medication. In addition, since most medications have a larger molecular size than urea, their resultant CL will likely be even lower: probably between 5 and 7.5 mL/min (0.08-0.13 mL/s). Therefore, medication dosing recommendations for the management of conditions other than peritonitis, reported for patients with estimated CL_{cr} or GFR of 10 to 15 mL/min (0.17-0.25 mL/s), are likely suitable for patients receiving peritoneal dialysis.[16]

Alternative Hemodialysis Modalities

Short-daily and nocturnal HD are two alternative HD techniques. Both modalities are administered 5 to 6 days a week but differ primarily in the duration of the treatment and blood-flow rate.[80] Overall small solute removal is more efficient if the frequency of HD is increased. Therefore, SDHD and NHD therapies yield different clearance values compared to intermittent three times per week HD. Furthermore, prolonged HD such as in the case of NHD, results in less rebound of medication concentrations after the termination of dialysis. This likely occurs because the rate of transfer from the peripheral to central compartment relative to the rate of diffusive removal is lower. Therefore, careful monitoring of pharmacotherapy is necessary when these newer modalities are used to avoid potential errors in designing medication dosing regimens.

Nocturnal Hemodialysis

NHD is performed over 6 to 8 hours on 5 to 6 nights per week.[80] There is a paucity of information related to medication dosing with this modality; however, the principles of medication dosing discussed above with intermittent HD can also be applied here. Although there is an increase in dialysis hours, which would suggest an increase in medication removal, the blood and dialysate flow rates are slower and thus clearance per unit of time will be less. This has been demonstrated with cefazolin where the cefazolin clearance during NHD was slightly lower (CL = 1.65 L/hr) than during high-flux intermittent HD (CL = 1.85 L/hr); however, a greater percentage of cefazolin was removed in 8 hours of NHD (80%) than conventional 4-hour high-flux HD (60%).[81]

Short-Daily Hemodialysis

SDHD involves 2 to 3 hours of dialysis performed 5 to 6 days per week.[80] As in the case with NHD, there is also limited information on medication dosing with this modality; however, the general principles of medication dosing for HD also apply here. In SDHD, the number of dialysis sessions per week and blood and dialysate flow rates are similar to intermittent HD, which may suggest similar medication removal. However, for certain medications (smaller size and decreased V_D, and protein binding) removal may be increased. For example, the cefazolin clearance rate in SDHD is slightly higher than the value observed during high-flux intermittent HD; the amount of cefazolin removed in 2 hours of SDHD is similar to that after 4 hours of high-flux HD.[82] Therefore, the same amount of medication given over the entire week for patients on intermittent HD could also be given to patients on SDHD but in smaller amounts administered more frequently. For instance, in intermittent HD, the cefazolin dose is typically 2 g IV after each HD for a total of 6 g/week; whereas in SDHD, the dose would be 1 g IV daily (ie, for 6 days) after each HD.

CONCLUSION

Patients with CKD often exhibit changes to pharmacokinetics and pharmacodynamics, and medication dosage regimen adjustment is often warranted in these patients. When available, the utilization of FDA or EMA medication dosage recommendations in official prescribing information should be used for the initiation of therapy in most clinical situations. However, when these guidelines are unavailable for the relevant clinical setting, the use of pharmacokinetic principles in conjunction with reliable population pharmacokinetic estimates may be used to determine the optimal medication dosage regimen. Prospective monitoring of serum concentrations for medications with a narrow therapeutic index should be undertaken whenever clinical therapeutic monitoring tools are available. The ultimate goal of medication dosage regimen adjustment in CKD is to individualize and optimize pharmacotherapeutic outcomes in this population to maximize therapeutic efficacy while minimizing unnecessary toxicity.

ABBREVIATIONS

α	constant relating the renal drug elimination rate constant to creatinine clearance

A_{b}	concentration of medication in blood going into the dialyzer (arterial side)
AKI	acute kidney injury
A_{p}	concentration of medication in plasma going into the dialyzer (arterial side)
AUC	area under the plasma concentration-time curve
$\mathrm{AUC}_{0\text{-}t}$	the area under the predialyzer plasma concentration-time curve during hemodialysis
BCRP	breast cancer resistance protein
BSA	body surface area
ΔC	change in plasma concentration
C_{aD}	plasma concentration after dialysis
C_{bD}	plasma concentration prior to the next dialysis session
CG	Cockcroft–Gault
CKD	chronic kidney disease
CKD-EPI	Chronic Kidney Disease Epidemiology Collaboration Equation
CL	clearance
$\mathrm{CL}_{\mathrm{D}}^{\mathrm{b}}$CLDb	dialyzer clearance from blood
$\mathrm{CL}_{\mathrm{CKD}}$	clearance of a medication in patients with impaired kidney function
$\mathrm{CL}_{\mathrm{cr}}$	creatinine clearance
CL_{D}	dialyzer clearance
$\mathrm{CL}_{\mathrm{filt}}$	renal filtration clearance
$\mathrm{CL}_{\mathrm{norm}}$	clearance of a medication in patients with normal kidney function
$\mathrm{CL}_{\mathrm{NR}}$	nonrenal clearance
$\mathrm{CL}_{\mathrm{D}}^{\mathrm{p}}$CLDp	dialyzer clearance from plasma
CL_{R}	renal clearance
$\mathrm{CL}_{\mathrm{reabsorption}}$	renal tubular reabsorption
$\mathrm{CL}_{\mathrm{RES}}$	residual clearance in a dialysis patient

$CL_{secretion}$	renal tubular secretion clearance
CL_T	total clearance
$C_{reported}$	patient's total phenytoin concentration reported by the laboratory
C_{max}	peak or maximum concentration
C_{min}	trough or minimum concentration
$C_{normal\ binding}$	total phenytoin concentration that would be observed if a patient had normal protein binding
C_{ss}	average steady-state plasma concentration
CYP	cytochrome P450
D_{CKD}	maintenance dose for a patient with impaired kidney function
D_{norm}	dose for a patient with normal kidney function
eCL_{cr}	estimated creatinine clearance
eGFR	estimated glomerular filtration rate
EMA	European Medicine Agency
ESKD	end-stage kidney disease
FDA	Food and Drug Administration
f_e	fraction of medication eliminated unchanged in the urine
f_u	fraction of medication unbound to plasma proteins
GFR	glomerular filtration rate
GI	gastrointestinal
HD	hemodialysis
IV	intravenous
k	elimination rate constant
k_a	absorption rate constant
k_{NR}	nonrenal elimination rate constant
KDIGO	Kidney Disease: Improving Global Outcomes

KF	ratio of the patient's CL_{cr} to the assumed normal value of 120 mL/min (2 mL/s)
MATE	multidrug and toxin extrusion protein
MIC	minimum inhibitory concentration
mRNA	m ribonucleic acid
MRP	multidrug resistance protein
MRSA	methicillin-resistant *Staphylococcus aureus*
NHD	nocturnal hemodialysis
OAT	organic anion transporter
OATP	organic anion transporting polypeptide
OCT	organic cation transporter
OCTN	organic cation and carnitine transporters
P-gp	P-glycoprotein
Q	kinetic parameter/dosage-adjustment factor
Q_b	blood flow through the dialyzer
Q_p	plasma flow through the dialyzer = Q_b (1 – hematocrit)
R	the total amount of medication recovered unchanged in the dialysate
SCr	serum creatinine
SDHD	short daily hemodialysis
t'	infusion time of medication
Δt	time in hours between two measured concentrations
$t_{1/2}$	half-life
$t_{1/2,\text{on HD}}$	half-life during dialysis
$t_{1/2,\text{off HD}}$	half-life off dialysis
τ_{CKD}	dosing interval in a patient with kidney failure
τ_{norm}	dosing interval in a patient with normal kidney function
t_{max}	time to peak concentration

UGT	uridine diphosphate-glucuronosyltransferase
V_{area}	volume of distribution area
V_b	blood concentration of medication leaving the dialyzer
V_β	volume of terminal phase (serum protein)
V_c	volume of the central compartment
V_D	volume of distribution
V_{ss}	volume of distribution at steady state

SELF-ASSESSMENT QUESTIONS

1. Which of the following is a source of variability in absorption of medications in patients with CKD?

    A. Increased pre-systemic metabolism

    B. Delayed gastric emptying

    C. Increased gastric acidity

    D. Decreased renal clearance

2. Which of the following is a potential mechanism by which the volume of distribution of medications is increased in patients with chronic kidney disease?

    A. Decreased plasma protein binding

    B. Decreased tissue binding

    C. Increased fluid excretion

    D. Decreased nonrenal clearance

3. Increased concentrations of α1-acid glycoprotein leads to a reduction in plasma protein binding of ______________ medications.

    A. Hydrophilic

    B. Lipophilic

    C. Acidic

    D. Basic

4. Renal clearance of a medication is a composite of all of the following pathways EXCEPT:

    A. Absorption

    B. Glomerular filtration

    C. Reabsorption

    D. Secretion

5. Metabolites of drugs may be pharmacologically active and may accumulate in patients with impaired kidney function. Which of the following medications has an active metabolite that may accumulate and lead to toxicity in patients with CKD?

    A. Aspirin

    B. Canagliflozin

    C. Midazolam

    D. Morphine

6. Which of the following pathways is NOT a major contributor to nonrenal clearance of medications?

A. Metabolism by cytochrome P450 (CYP) enzymes

B. Metabolism by uridine diphosphate-glucuronosyltransferase (UGT) enzymes

C. Transport by organic anion transporter polypeptides (OATP)

D. Tubular secretion by the organic anion transporters (OATs)

7. References to primary literature are provided in which of the following sources of medication information?

A. Aronoff's *Drug Prescribing in Renal Failure*

B. *The Renal Drug Handbook*

C. *Lexicomp*

D. *American Hospital Formulary Service* (AHFS)

8. Which of the following statements regarding the Rowland and Tozer method for estimating the total body clearance (CL_T) of medications in patients with CKD is CORRECT?

A. This method can be used for medications with known alternations in their metabolism among CKD patients.

B. The fraction of the medication that is eliminated renally unchanged (fe) in subjects with normal kidney function must be known.

C. It is applicable when the medication obeys nonlinear kinetic principles.

D. The change in CL must be disproportional to CL_{cr}.

9. A patient with CKD who has a CL_{cr} of 20 mL/min (0.33 mL/s) is to receive an antibiotic that has a fe of 85%. Based on this information, calculate the kinetic parameter/dosage-adjustment factor (Q).

A. 0.15

B. 0.29

C. 0.39

D. 0.5

10. A patient with CKD who has a CL_{cr} of 50 mL/min (0.83 mL/s) is to receive a medication that has an fe of 80%. The normal dose is 500 mg by mouth every 6 hours. Based on this information, calculate the most appropriate and practical adjusted dosage regimen for this patient.

A. 250 mg every 6 hours

B. 250 mg every 12 hours

C. 500 mg every 6 hours

D. 500 mg every 12 hours

11. Which of the following statements regarding the effects of dose and dosing interval adjustments in patients with impaired kidney function is CORRECT?

A. If the dose is reduced while the dosing interval remains unchanged, then the peak will be higher and the trough lower.

B. If the dose remains unchanged while the dosing interval is increased, then the peak and trough concentrations in patients with impaired kidney function will be similar to those in patients with normal kidney function.

C. If the dose is reduced while the dosing interval remains unchanged, then the peak and trough concentrations in patients with impaired kidney function will be similar to those in patients with normal kidney function.

D. If the dose remains unchanged while the dosing interval is increased, then the peak will be higher and the trough lower.

12. A 58-year-old man weighing 80 kg and with a measured CL_{cr} of 15 mL/min (0.25 mL/s) is to receive intravenous ciprofloxacin. The usual dose of ciprofloxacin is 500 mg every 12 hours for patients with normal kidney function. The relationship between ciprofloxacin clearance (CL_T) and kidney function is the following:

$$CL_T = 2.83\,(CL_{cr} \text{ in mL/min}) + 363$$

$CLT = 2.83 (CLcr in mL/min) + 363$

A. 250 mg every 12 hours

B. 250 mg every 24 hours

C. 500 mg every 24 hours

D. 500 mg every 48 hours

Based on this information, calculate the most appropriate and practical adjusted dosage regimen for this patient. (Note: CL_{cr} results in mL/s must be divided by 0.0167 to use this equation.)

13. Which of the following statements regarding medication dialyzability by peritoneal dialysis is CORRECT?

A. Medications that are unionized at physiologic pH will diffuse across the peritoneal membrane more slowly than ionized compounds.

B. Blood flow and peritoneal membrane surface area are intrinsic properties of the peritoneal membrane that affect medication removal.

C. Peritoneal dialysis is more effective than hemodialysis at removing medications.

D. Peritoneal medication clearance is higher for extensively protein bound medications

14. Which of the following medications is most likely to be removed by high flux hemodialysis?

A. Amlodipine (MW = 567 Da; V_D = 21.0 L/kg; plasma protein binding > 95%)

B. Atenolol (MW = 266 Da; V_D = 1.1 L/kg; plasma protein binding = 3%)

C. Clindamycin (MW= 476 Da; V_D = 0.8 L/kg; plasma protein binding= 94%)

D. Apixaban (MW = 460 Da; V_D = 0.3 L/kg; plasma protein binding = 87%)

15. Which of the following statements regarding medication removal by alternative hemodialysis modalities is CORRECT?

A. Medication removal during nocturnal hemodialysis is greater than during standard intermittent hemodialysis

B. Medication removal during nocturnal hemodialysis is negligible

C. Medication removal during short daily hemodialysis is less than standard intermittent hemodialysis

D. Medication removal during short daily hemodialysis is negligible

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Decreased GI motility can occur in CKD patients secondary to diabetic gastroparesis and may delay t_{max} and decrease C_{max}, thereby altering a medication's absorption. See the "Absorption and Bioavailability" section for more information.

2. **C.** Protein binding limits medication distribution, as only unbound or "free" medication is able to cross cellular membranes and distribute outside the vascular space. A decrease in plasma protein binging thus leads to increased distribution of medication. See the "Distribution" section for more information.

3. **D.** α1-Acid glycoprotein is major drug-binding plasma protein that primarily binds basic medications. Since it exhibits increased plasma concentrations in CKD, the unbound fraction of basic medications may be dramatically decreased leading to decreased V_D in CKD patients.

4. **A.** Renal clearance is a composite of all renal excretory functions, namely filtration, tubular secretion, and tubular reabsorption. Absorption is not involved in renal clearance. See the "Renal Clearance" section for more information.

5. **D.** Morphine undergoes hepatic metabolism into active metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), which readily cross the blood-brain barrier, bind to opiate receptors, and exert strong analgesic effects. In CKD patients, the clearance of M3G and M6G is decreased, potentially resulting in prolonged narcosis and respiratory depression. See the "Accumulation of Metabolites" section for more information.

6. **D.** The OATs are predominantly involved in basolateral uptake of medications into renal tubular cells from the plasma, thereby contributing to tubular secretion and net renal clearance of medications. Major nonrenal clearance pathways include oxidative metabolism by CYPs, conjugative metabolism by UGTs, and transport by OATPs.

7. **A.** Although it is infrequently updated, Aronoff's *Drug Prescribing in Renal Failure* exclusively focuses on medication dosing in patients with impaired kidney function and provides references to primary literature.

8. **B.** The method of Rowland and Tozer is useful for determining CL_T provided that f_e for subjects with normal kidney function is known. This approach assumes that the change in CL_T and k are proportional to eCL_{cr}, that kidney disease does not alter the medication's metabolism, that any metabolites that are formed are inactive and nontoxic, and that the medication obeys first-order (linear) one-compartment kinetic principles. See the "Medication Dosage Regimens for Non-Dialysis CKD Patients" section for more information.

9. **B.** Since the equation describing the relationship between kidney function and CL_T is not provided, the method of Rowland and Tozer can be used to determine the dosage adjustment factor (Q), as follows:

$$Q = 1 - [f_e(1 - \mathrm{KF})]$$
$$\mathrm{KF} = \mathrm{CL}_{\mathrm{CR\,(patient)}}/\mathrm{CL}_{\mathrm{CR\,(normal)}} = 20\,\mathrm{mL/min}\,/\,120\,\mathrm{mL/min} = 0.167$$
$$Q = 1 - [0.85(1 - 0.167)] = 0.29$$

Q=1–[fe(1–KF)]KF=CLCR(patient)/CLCR(normal)=20 mL/min / 120 mL/min=0.167Q=1–[0.85(1–0.167)]=0.29

10. **D.** Since the equation describing the relationship between kidney function and CL_T is not provided, the method of Rowland and Tozer can be used to determine the dosage adjustment factor (Q), as follows:

$$Q = 1 - [f_e(1 - \mathrm{KF})]$$
$$\mathrm{KF} = \mathrm{CL}_{\mathrm{CR\,(patient)}}/\mathrm{CL}_{\mathrm{CR\,(normal)}} = 50\,\mathrm{mL/min}\,/\,120\,\mathrm{mL/min} = 0.42$$
$$Q = 1 - [0.8\,(1 - 0.42)] = 0.54$$

Q=1–[fe(1–KF)]KF=CLCR(patient)/CLCR(normal)=50 mL/min / 120 mL/min=0.42Q=1–[0.8 (1–0.42)]=0.54

Increasing the dosing interval is the approach used most commonly to adjust dosage regimens in patients with impaired kidney function, so apply Q to the interval:

$$\tau_{\mathrm{CKD}} = \tau_{\mathrm{norm}}/Q$$
$$\tau_{\mathrm{CKD}} = 6\,\mathrm{hours}/0.54 = 11.1\,\mathrm{hrs}$$

τCKD=τnorm/QτCKD=6 hours/0.54=11.1 hrs

Use a practical interval, so recommend adjusted dosing regimen of 500 mg every 12 hours.

11. **B.** If the dose is decreased and the dosing interval remains unchanged, then the average steady-state concentration will be unchanged but the peaks will be lower and the troughs will be higher. Conversely, if the dosing interval is increased and the dose remains unchanged, then the average steady-state, peak, and trough concentrations in the patient with impaired kidney function will be similar to those in the patient with normal kidney function. See the "Designing Adjusted Renal Dosage Regimens" section for more information.

12. **C.** Since the equation describing the relationship between kidney function and CL_T is provided, it can be used to calculate the CL_T in the patient and to derive the dosage adjustment factor (Q), as follows:

$$CL_{T(\text{patient})} = 2.83(15\,\text{mL/min}) + 363 = 405\,\text{mL/min}$$
$$CL_{T(\text{normal})} = 2.83(120\,\text{mL/min}) + 363 = 703\,\text{mL/min}$$
$$Q = 405/703 = 0.57$$

CLT(patient) = 2.83(15 mL/min)+363 = 405 mL/minCLT(normal) = 2.83(120 mL/min)+ 363 = 703 mL/minQ = 405/703 = 0.57

Increasing the dosing interval is the approach used most commonly to adjust dosage regimens in patients with impaired kidney function, so apply Q to the interval:

$$\tau_{\text{CKD}} = \tau_{\text{norm}}/Q$$
$$\tau_{\text{CKD}} = 12\,\text{hours}/0.57 = 21\,\text{hrs}$$

τCKD=τnorm/QτCKD=12 hours/0.57 = 21 hrs

Use a practical interval, so recommend adjusted dosing regimen of 500 mg every 24 hours.

13. **B.** The intrinsic properties of the peritoneal membrane that affect medication removal include blood flow and peritoneal membrane surface area. There is an inverse relationship between peritoneal clearance of medications and protein binding. Medications that are ionized at physiologic pH will diffuse across the membrane more slowly than unionized compounds. In general, hemodialysis is more effective in removing medications than peritoneal dialysis.

14. **B.** Medication-related factors that affect dialyzability include the molecular weight, degree of protein binding, and V_D. High-flux hemodialysis membranes allow for the passage of medications that have a molecular weight up to 20,000 Da. Medications that are highly protein bound (ie, >90%) are not well dialyzed. Finally, medications that are widely distributed, with V_D greater than 2 L/kg, are poorly removed by HD. See the "Principles of Hemodialytic Clearance of Medications" section for more information.

15. **A.** The blood and dialysate flow rates are typically slower for nocturnal hemodialysis than standard intermittent hemodialysis and thus clearance per unit of time will be less. However, since nocturnal hemodialysis is performed more frequently and for longer duration per session, it may result in an increase in medication removal compared to standard intermittent hemodialysis. See the "Alternative Hemodialysis Modalities" section for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 68: Disorders of Sodium and Water Homeostasis

Katherine H. Chessman; Jason S. Haney

KEY CONCEPTS

KEY CONCEPTS

① Maintenance of normal blood volume and serum osmolality is essential for cellular function and is tightly regulated in the human body. Simply put, water balance determines serum sodium concentration, and sodium balance determines volume status.

② Total body water (TBW) ranges from 45% to 80% of body weight depending on sex, age, gestational age, and disease states and is distributed primarily into two compartments: the intracellular compartment or intracellular fluid (ICF; two-thirds [67%] of TBW) and the extracellular compartment or extracellular fluid (ECF; one-third [33%] of TBW).

③ Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), is synthesized in the hypothalamus and secreted by the posterior pituitary in response to both osmotic (serum sodium greater than 135 mEq/L [mmol/L]) and non-osmotic regulators to maintain water balance.

④ Hyponatremia, defined as a serum sodium concentration less than 135 mEq/L (mmol/L), is the most common electrolyte abnormality encountered in clinical practice in both adults and children and is associated with significant morbidity and mortality.

⑤ Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion.

⑥ Hypovolemic hypotonic hyponatremia is common in patients taking thiazide diuretics.

⑦ Euvolemic (isovolemic) hypotonic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased TBW and ECF volume and is most often caused by the syndrome of inappropriate ADH secretion (SIADH).

⑧ Hyponatremia with ECF volume expansion (hypervolemia) occurs in conditions in which sodium and water excretion is impaired such as heart failure, cirrhosis, or nephrotic syndrome.

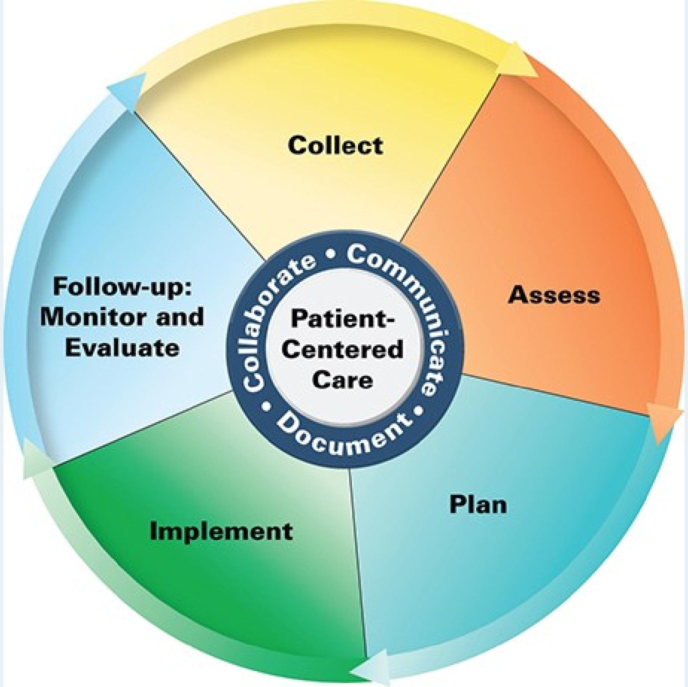
⑨ The brain's adaptation to chronic serum hypoosmolality or hyperosmolality leads to neurologic symptoms when either hyponatremia (hypoosmolality) or hypernatremia (hyperosmolality) is corrected too rapidly.

⑩ Hypernatremia, defined as a serum sodium concentration greater than 145 mEq/L (mmol/L), is always associated with hypertonicity and intracellular dehydration, resulting from a water deficit relative to ECF sodium content.

⑪ Edema, defined as a clinically detectable increase in interstitial fluid volume, is usually due to heart, kidney, or liver failure or a combination of these conditions; although, it can develop with a rapid decrease in serum albumin concentration along with excess fluid intake such as seen in the setting of burns or trauma.

PATIENT CARE PROCESS

Patient Care Process* for the Management of Disorders of Sodium and Water Homeostasis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient history (eg, medical, surgical, diet, recent gastrointestinal [GI] losses; see Tables 68-2 and 68-7)
- Current medications (eg, diuretics, intravenous [IV] fluids, sodium-containing therapies; see Tables 68-3 and 68-8)
- Objective data
  - Body weight (current and historical)
  - Recent intake/output
  - ECF volume status (eg, blood pressure [BP], mucous membranes, skin turgor, cardiopulmonary examination, level of consciousness; see Figs. 68-1 and 68-3)
  - Labs (eg, serum osmolality, electrolytes, glucose, protein, lipids; urine osmolality, sodium, and potassium; thyroid function tests)

Assess

- Chronicity and severity of the disorder
- Potential causative underlying disorders (eg, diarrhea, central nervous system [CNS] disorders, pulmonary disease, cirrhosis, nephrotic syndrome, polydipsia, diabetes insipidus; see Tables 68-2 and 68-7)
- Dysregulated sodium- or fluid-related complications (eg, BP variations, CNS changes, edema; see Clinical Presentation boxes and Tables 68-2 and 68-7)
- Current medications that may affect or worsen the disorder (see Tables 68-2, 68-3, 68-7, and 68-8)
- Goals for sodium and/or volume status and achievement of the goals

Plan[*]

- Treat the underlying cause of the disorder, if possible
- Develop therapy regimen, including specific medication(s), dose, route, frequency, and duration (see Tables 68-4–68-6 and 68-9–68-12; Figs. 68-4–68-6)
- Balance risks of underlying disorder versus risk of too rapid or overcorrection (see Table 68-4)
- Specify continuation and discontinuation of existing therapies
- Tailor dietary modifications (eg, water and solute intake) and weight management
- Establish monitoring parameters, including efficacy (serum sodium, volume status, urine output), safety (rate of serum sodium correction, medication-specific adverse reactions), and time frame
- Provide patient education (purpose of treatment, dietary and lifestyle modification, medications, self-monitoring of weight and volume status)
- Refer to other providers, when appropriate (eg, physician, dietitian)

Implement[*]

- Provide patient education regarding all elements of treatment plan
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Attainment of sodium and/or volume status goals
- Presence of adverse medication reactions
- Need for long-term management if disorder cannot be corrected
- Patient adherence to treatment plan using multiple sources of information

[*] Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Read and evaluate the case presented in Chapter 57 “Syndrome of Inappropriate Antidiuretic Hormone Release: A Sudden Change of Mind Level I. In: Schwinghammer TL, Koehler JM, Borchert JS, Slain D, Park SK. eds. *Pharmacotherapy Casebook: A Patient-Focused Approach, 11e*. McGraw Hill; 2020.” Available at https://accesspharmacy.mhmedical.com/content.aspx?bookid=2868&sectionid=242182677.

This activity is useful to enhance student understanding regarding the COLLECT, ASSESS, PLAN, and IMPLEMENT steps in the patient care process.

INTRODUCTION

① Maintenance of normal blood volume and serum osmolality is essential for cellular function and is tightly regulated in the human body. Simply put, water balance determines serum sodium concentration, and sodium balance determines volume status. Adequate blood volume is required for effective tissue perfusion which is required to deliver oxygen and nutrients to and remove metabolic waste products from tissues. Serum osmolality, determined primarily by the serum sodium concentration, is an important determinant of ICF volume. Maintaining normal ICF volume is particularly critical in the brain, which is 80% water, and where alterations, especially rapid changes, can result in significant dysfunction, and even death.

Homeostatic mechanisms for controlling blood volume focus on controlling sodium balance, and, in contrast, homeostatic mechanisms for controlling serum osmolality (serum sodium concentration) focus on controlling water balance. Disorders of sodium and water balance are common, caused by a variety of diseases, conditions, and medications, and potentially serious. This chapter reviews the etiology, pathophysiology, clinical presentation, and treatment options for disorders of sodium and water homeostasis.

SODIUM AND WATER HOMEOSTASIS

The average daily sodium intake of Americans consuming a typical western diet usually exceeds the recommendations or chronic disease reduction (CDRR) levels established by the US Department of Agriculture: adults and children older than 13 years, 2.3 g; 9 to 13 years, 1.8 g; 4 to 8 years, 1.5 g; 1 to 3 years, 1.2 g; and, infants and young children 6 to 11 months, 0.37 g (Adequate Intake, AI).[1] Excessive sodium intake is a major risk factor for hypertension as BP rises with increased sodium intake. Appropriately functioning kidneys excrete excess sodium to maintain the serum sodium concentration and osmolality within a tight range. The kidney can also conserve sodium (urine sodium less than 30 mEq/L [mmol/L]) during periods of low sodium intake or in the presence of excessive losses. Both hypo- and hypernatremia are conditions of altered serum tonicity and cell volume that reflect a change in the ratio of total exchangeable body sodium to TBW.

② TBW ranges from 45% to 80% of body weight depending on sex, age, gestational age, and disease states and is distributed primarily into two compartments: the intracellular compartment or intracellular fluid (ICF; two-thirds [67%] of TBW) and the extracellular compartment or extracellular fluid (ECF; one-third [33%] of TBW). The serum (plasma) volume is approximately 17% of the ECF volume. Sodium contributes more than 90% of the ECF osmolality; whereas ICF osmolality is primarily determined by the ICF potassium concentration. The extra- and intracellular sodium and potassium concentrations are maintained by the sodium–potassium–adenosine triphosphatase (Na^+-K^+-ATPase) pump. Because most cell membranes are freely permeable to water, the free flow of water between compartments ensures that the ICF and ECF osmolalities remain equal.

Effective osmoles are solutes that cannot freely cross cell membranes, such as sodium and potassium, which are kept in their respective compartments by the Na^+-K^+-ATPase pump. The ECF concentration of effective osmoles determines its tonicity, which directly affects water distribution between the ECF and ICF. Addition of an isotonic solution (eg, 0.9% NaCl) to the ECF will result in no change in ICF volume because there will be no change in the effective ECF osmolality. However, addition of a hypertonic solution (eg, 3% NaCl) to the ECF will result in a decrease in ICF (cell) volume. Conversely, addition of a hypotonic solution (eg, 0.45% NaCl) to the ECF will result in an increase in ICF (cell) volume. Thus, administration of both hypertonic and hypotonic solutions can result in cell crenation or hemolysis, respectively. Table 68-1 summarizes the composition and osmolality of commonly used IV solutions and their expected distribution into the ICF and ECF compartments following administration.

TABLE 68-1

Composition of Common IV Solutions

								Distribution		
Solution	Dextrose g/dL (kcal/L)	$[Na^+]$ (mEq/L or mmol/L)	$[K^+]$ (mEq/L or mmol/L)	$[Cl^-]$ (mEq/L or mmol/L)	Other (mEq/L)	Osmolality (mOsm/kg or mmol/kg)	Tonicity	% ECF	% ICF	Free water (mL/L)

[g] Hypertonic solution; results in osmotic removal of water from the ICF

Edelman's equation (simplified) defines serum sodium (Na_S) as a function of the total exchangeable sodium and potassium in the body and the TBW:

$$Na_s = Na_{totalbody} + K_{totalbody} / TBW$$

Nas=Natotalbody+Ktotalbody/TBW

where $Na_{total\ body}$ is the total body sodium content; $K_{total\ body}$ is the total body potassium content; and TBW is the total body water (TBW) in liters.[2,3] The usual serum sodium concentration (135-145 mEq/L [mmol/L]) is tightly regulated and thus usually varies by no more than 3%. Serum sodium regulation occurs via mechanisms that control serum osmolality and blood volume. The kidney regulates water excretion through a hypothalamic feedback mechanism, such that the serum osmolality remains relatively constant (275-290 mOsm/kg [mmol/kg]) despite day-to-day variations in water intake. While serum osmolality is primarily determined by the sodium concentration, abnormally high glucose and blood urea nitrogen (BUN) concentrations may contribute significantly. Glucose is an effective osmole, but BUN is not; thus, elevated osmolality due to these two substances will have differing effects. Serum osmolality can be estimated as follows:

$$Osm_s = (2 \times Na_s) + (glucose_s / 18) + (BUN / 2.8)$$

Osms=(2×Nas)+(glucoses/18)+(BUN/2.8)

where Osm_S is the serum osmolality in mOsm/kg [mmol/kg]; Na_S is the serum sodium concentration in mEq/L; $glucose_S$ is the serum glucose concentration in mg/dL; BUN is the BUN concentration in mg/dL; and 18 and 2.8 are the factors needed to convert from a weight measurement (mg/dL) to a concentration (mmol/L) for glucose and BUN, respectively. Thus, when using SI units, the equation becomes

$$Osm_s = (2 \times Na_s) + glucose_s + BUN$$

Osms=(2×Nas)+glucoses+BUN

where Osm_S is the serum osmolality in mmol/kg; and Na_S, $glucose_S$, and BUN are the respective concentrations in mmol/L.

③ Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), is synthesized in the hypothalamus, and secreted by the posterior pituitary in response to both osmotic (serum sodium greater than 135 mEq/L [mmol/L]) and non-osmotic regulators to maintain water balance. When the serum osmolality increases by as little as 1% to 2%, AVP is released and binds to the arginine vasopressin 2 (V_2) receptor, a G protein-coupled receptor, on the basolateral membrane of principal cells lining the renal collecting duct, resulting in the insertion of water channels (aquaporin 2, AQP2) into both the apical cell membrane of the collecting duct principal cells and intracellular vesicles below the apical membrane increasing permeability.[2,4] Water can then pass through the cell into the peritubular capillary space where it is reabsorbed into the systemic circulation. A maximally concentration urine (1200 mOsm/L) will be formed when the serum sodium concentration is 145 mEq/L (mmol/L).[2] AVP release also stimulates thirst as an additional means to return serum osmolality toward normal. The combined effect of increased water intake (response to thirst) and decreased water excretion (kidney's response to AVP) results in a decrease in the serum osmolality. Once the serum osmolality is restored to normal, AVP secretion is inhibited, AQP2 water channels are retrieved, water permeability returns to the usual low state, and renal excretion of solute-free water (aquaresis) occurs.

While AVP secretion is regulated primarily by osmolality, non-osmotic AVP release occurs when the brain's osmoreceptors detect as little as a 6% to 10% reduction in the effective circulating volume or arterial BP. The effective circulating volume is the portion of the ECF responsible for organ perfusion. A decrease in the effective circulating volume (more accurately, the arterial BP associated with that volume) activates arterial baroreceptors in the carotid sinus and glomerular afferent arterioles, resulting in stimulation of the renin–angiotensin system and increased angiotensin II synthesis. Angiotensin II stimulates both non-osmotic AVP release and thirst. This non-osmotic volume stimulus can override osmotic AVP inhibition. Water conservation then restores the effective circulating volume and BP at the expense of producing a decreased serum osmolality and hyponatremia.[2] Both hypo- and hypernatremia can be associated with either high, low, or normal ECF sodium or volume. To understand treatment options, differentiating between *dehydration* and *hypovolemia* is important. Dehydration refers to a loss of TBW producing hypertonicity while hypovolemia (volume depletion) is a symptomatic ECF volume deficit. It is important to note that volume depletion and dehydration can exist independently or concurrently.

Often these terms are used interchangeably, but they are different processes requiring different types and rates of fluid replacement.[5]

HYPONATREMIA

Epidemiology and Etiology

④ Hyponatremia, defined as a serum sodium concentration less than 135 mEq/L (mmol/L), is the most common electrolyte abnormality encountered in clinical practice in both adults and children and is associated with significant morbidity and mortality.[4] It affects 3 to 6 million persons and 1 million hospitalized patients yearly.[6,7] Although the prevalence is not well established and varies with the patient population studied, it has been estimated to be 15% to 30% of hospitalized patients.[6,7] In one study, the prevalence of mild hyponatremia (serum sodium concentration less than 136 mEq/L [mmol/L]) in hospitalized patients was 42% (28% on admission, 14% during admission); 6.2% of patients evaluated (2.5% on admission, 3.7% during admission) had values less than 126 mEq/L (mmol/L); and, 1.2% (0.5% on admission, 0.7% during admission) had a serum sodium concentration less than 116 mEq/L (mmol/L).[8] The prevalence of hyponatremia in the intensive care unit (ICU) is 30% to 40% with an admission serum sodium less than 130 mEq/L (mmol/L) in approximately 14%.[9] In hospital-based ambulatory care clinics and community clinics, the prevalence of hyponatremia (serum sodium concentration less than 136 mEq/L [mmol/L]) is 21% and 1.7% to 9.2%, respectively.[8,10] Medication-induced hyponatremia, especially that associated with thiazide diuretics[11] and psychotropic medications,[12–14] is common.

Advancing age is a risk factor for hyponatremia, independent of sex.[10,15,16] Residents in nursing homes have a twofold higher incidence of hyponatremia than that observed in age-matched, community-dwelling individuals. More than 75% of these hyponatremic episodes were precipitated by increased intake of hypotonic fluids either orally or through enteral feedings or IV fluids.[17] Similarly, ingestion of excessive volumes of hypotonic fluids (water, sports drinks) has been identified as a key risk factor in the development of exercise-associated hyponatremia occurring during or up to 24 hours after prolonged physical activity. Men and women are at an equal risk for developing exercise-induced hyponatremia when rates are adjusted based on body mass index (smaller body size) and racing time (longer times).[18] Hyponatremia is also the most common electrolyte abnormality seen in pregnancy, frequently seen in patients with hyperemesis gravidarum and preeclampsia.[19]

Recognition of the high prevalence of hyponatremia is essential because this condition is associated with significant morbidity and mortality.[7,9,19–22] Even in asymptomatic patients, chronic hyponatremia has been associated with decreased cognitive function and an increased risk of frailty, falls, fractures, and bone loss, particularly in older adults.[23–26] In patients with hyponatremia, transient or permanent brain dysfunction can result from either acute effects of hypoosmolality or too rapid correction.

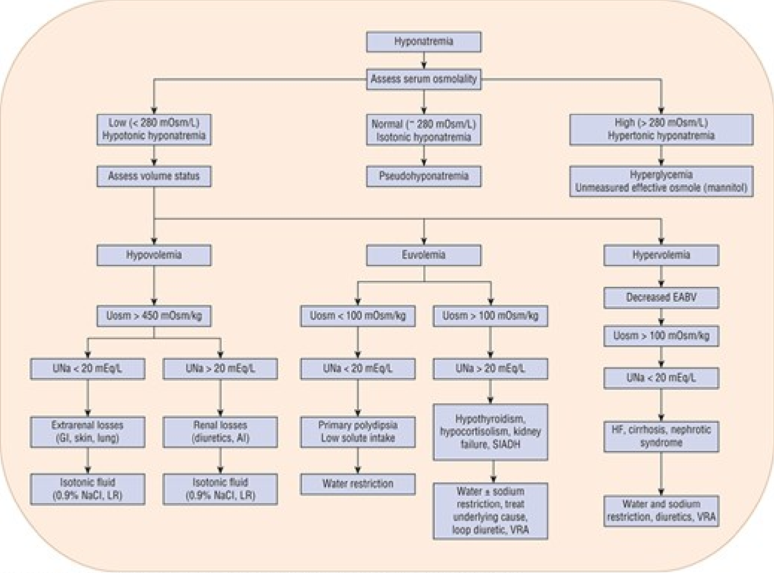
⑤ Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion. The kidney normally has the capacity to excrete large volumes of dilute urine after ingestion of a water load. Non-osmotic AVP release, however, can lead to water retention and a decrease in the serum sodium concentration, despite a decrease in ECF and ICF osmolality. Causes of non-osmotic AVP release include hypovolemia and a decreased effective circulating volume (eg, chronic heart failure [HF], nephrotic syndrome, cirrhosis). The syndrome of inappropriate antidiuretic hormone secretion (SIADH), a common cause of hyponatremia, is associated with some cancers, CNS damage, certain lung conditions, medications, and primary or psychogenic polydipsia.

Pathophysiology

Hyponatremia can be associated with normal, increased, or decreased serum osmolality, depending on its cause. Figure 68-1 provides an algorithm for the assessment and treatment of patients with non-emergent hyponatremia.[2,4]

FIGURE 68-1

Algorithm for the assessment and treatment of non-emergent hyponatremia. (AI, adrenal insufficiency; EABV, effective arterial blood volume; GI, gastrointestinal; HF, heart failure; LR, lactated Ringers; NaCl, sodium chloride; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; UNa, urine sodium concentration [values in mEq/L are numerically equivalent to mmol/L]; UOsm, urine osmolality [values in mOsm/kg are numerically equivalent to mmol/kg]; VRA, vasopressin receptor antagonist.)



Hyponatremia

Isotonic Hyponatremia

Hyponatremia (expected low osmolality) with a normal measured serum osmolality (*osmol gap*) can be seen in the setting of markedly elevated serum lipids (hyperlipidemia) or proteins (eg, hyperproteinemia, multiple myeloma) when flame photometry or indirect potentiometry is used to measure the sodium concentration. (Fig. 68-1) This *pseudohyponatremia* is an artifact because elevated lipids or proteins account for a larger than usual proportion of the total sample volume, reducing the percentage of water in the serum (Fig. 68-2). Because sodium is distributed in the water component only, the measured serum sodium concentration is falsely decreased, and the calculated osmolality will be low. The measurement of serum osmolality is not affected, leading to a discrepancy between the calculated and measured serum osmolality (*osmolal gap*). Pseudohyponatremia is not seen when the sodium concentration is measured via direct potentiometry using ion-selective electrodes as is most often done in current laboratory practice, including blood gas analyzers because it does not involve sample dilution. Treatment of *hyponatremia* in a case of pseudohyponatremia can lead to serious consequences.[27]

FIGURE 68-2

Elevated serum lipids or proteins result in a larger discrepancy between the volume of the sample and serum water, which leads to a falsely low measurement of the serum sodium concentration when using flame photometry. (S_{Na}, serum sodium concentration [values in mEq/L are numerically equivalent to mmol/L].)

Hypertonic Hyponatremia

Hypertonic (increased serum osmolality) hyponatremia is due to the presence of excess effective osmoles (other than sodium) in the ECF (Fig. 68-1). Significant hyperglycemia is the most frequent cause. An elevated serum glucose concentration initially causes water diffusion from cells (ICF) into the ECF, thereby decreasing the ICF volume, expanding the ECF volume, and diluting the existing sodium resulting in hyponatremia. The increased ECF volume results in increased urine output (polyuria) which triggers the thirst mechanism (polydipsia). If the hyperglycemia is not corrected and/or extra fluid is not ingested, hypovolemia develops due to excessive urinary losses.

The volume of distribution (V_d) of glucose is a complex function of insulin activity, glucose distribution time, ECF volume, and glucose concentration. Using a clinically relevant glucose V_d of 0.3 to 0.5 L/kg, one would predict a 1.5 to 1.9 mEq/L (mmol/L) decrease in the serum sodium concentration for every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration above 100 mg/dL (5.6 mmol/L) or 0.29 mmol/L decrease for every 1 mmol/L increase, and the serum osmolality will increase by 2 mOsm/kg (mmol/kg).[5,28] This correction is only an estimate because of the variability in the V_d of glucose, and clinical practice guidelines recommend simplifying to 1.6 mg/dL as the correction factor using the equation:

$$\text{SNa}_{\text{corrected}}=\text{SNa}_{\text{measured}}+(1/6\times\text{glucose}_{\text{measured}}/100)$$
SNacorrected=SNameasured+(1/6×glucosemeasured/100)

where $\text{SNa}_{\text{corrected}}$ is the serum sodium (mg/dL) corrected for hyperglycemia; $\text{SNa}_{\text{measured}}$ is the measure serum sodium (mg/dL); and $\text{glucose}_{\text{measured}}$ is the measured serum glucose in mg/dL.[20]

Alternatively, for glucose and sodium expressed in units of mmol/L the following equation is used:

$$SNa_{corrected} = SNa_{measured} + 0.29 \times (glu\cos e_{measured} - 5.6)$$
SNacorrected=SNameasured + 0.29×glucosemeasured - 5.6

where $\text{SNa}_{\text{corrected}}$ is the serum sodium (mmol/L) corrected for hyperglycemia; $\text{SNa}_{\text{measured}}$ is the measure serum sodium (mmol/L); and $\text{glucose}_{\text{measured}}$ is the measured serum glucose in mmol/L.

The presence of other effective osmoles (eg, mannitol) can also cause hypertonic hyponatremia. The presence of an unmeasured osmole should be suspected in patients with a normal glucose concentration and hyWhpertonic hyponatremia when there is a significant osmolal gap.

Hypotonic Hyponatremia

Hypotonic (decreased osmolality) hyponatremia is the most common form of hyponatremia and has many potential causes (Table 68-1). Assessment of ECF volume status is important in the evaluation of a patient with hypotonic hyponatremia. Categorization into one of three groups (decreased, increased, or clinically normal ECF volume) is the essential first step in identifying the pathophysiologic mechanism(s) responsible for the hyponatremia and developing an appropriate treatment plan.

TABLE 68-2

Characteristics of Hypotonic Hyponatremic States

Characteristics	Hypovolemic Hyponatremia	Euvolemic (Isovolemic) Hyponatremia	Hypervolemic Hyponatremia
Water and sodium	Sodium loss >> water loss	Water gain only	Water gain > sodium gain
Causes	Renal: thiazide diuretics Nonrenal: diarrhea, cerebral salt-wasting	SIADH	Heart failure Liver cirrhosis Kidney failure
Effect on TBW	↓↓	↑	↑↑
Effect on TBNa	↓	↔	↑↑
Additional laboratory findings	Renal: UOsm high, UNa high Nonrenal: UOsm high, UNa low	Renal: UOsm low, UNa variable Nonrenal: UOsm high, UNa variable	UOsm high, UNa high
Clinical presentation	Orthostasis, hypotension, tachycardia, dry mucous membranes, CNS changes	Depends on severity of hyponatremia: seizures, lethargy	Peripheral and pulmonary edema, variable BP
Treatment	0.9% NaCl until vital signs stable; *maintenance* fluids to continue fluid deficit replacement; sodium replacement if cerebral salt wasting; VRA contraindicated	Water restriction, demeclocycline, loop diuretics, VRA, urea	Sodium and water restriction, loop diuretic, VRA, urea

CNS, central nervous system; NaCl, sodium chloride; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TBW, total body weight; UNa, urine sodium; UOsm, urine osmolality; VRA, vasopressin receptor antagonist.

Hypovolemic Hypotonic Hyponatremia

Most patients with ECF volume contraction have lost fluids that are hypotonic relative to the serum and thus may become transiently hypernatremic. This situation includes patients with fluid losses caused by diarrhea, excessive sweating, and diuretics. This transient hypernatremic hyperosmolality results in osmotic AVP release and thirst. If sodium and water losses continue, the resultant hypovolemia results in more AVP release. Patients who then drink water (a hypotonic fluid) or who are given hypotonic IV fluids retain water, and hyponatremia develops. These patients will typically have a concentrated urine (urine osmolality greater than 450 mOsm/kg [mmol/kg]), reflecting AVP action. The urine sodium concentration will be less than 30 mEq/L (mmol/L) when sodium losses are extrarenal (eg, diarrhea, vomiting), and greater than 30 mEq/L (mmol/L) with renal sodium losses (eg, thiazide diuretics, adrenal insufficiency); although, urine sodium concentration is also affected by solute intake.[4,20]

⑥ Hypovolemic hypotonic hyponatremia is common in patients taking thiazide diuretics.[6,11] Thiazide diuretic-induced hyponatremia is usually mild and relatively asymptomatic but can be severe. Hyponatremia typically develops within 2 weeks of diuretic initiation but can occur at any time during therapy, particularly after dosage increases or if other causes of hyponatremia are present. Older women are at the greatest risk for thiazide diuretic-induced hyponatremia.[6,11]

Thiazide diuretic-induced hyponatremia is related to a balance of direct and indirect effects. These agents block sodium reabsorption in the distal tubules of the renal cortex, thereby increasing sodium and water removal from the body. The resultant decrease in effective circulating volume stimulates AVP release, resulting in increased free water reabsorption in the collecting duct, as well as increased water intake because of thirst stimulation. Hyponatremia develops when the net result of these effects is the loss of more sodium than water.

Conversely, hyponatremia occurs infrequently with loop diuretics due to their different site of action. Loop diuretics block sodium reabsorption in the ascending limb of the loop of Henle. This action decreases medullary osmolality; thus, when loop diuretic use decreases the effective circulating volume and stimulates AVP release, less water reabsorption occurs in the collecting ducts than would occur with normal medullary osmolality. Thiazide diuretics do not alter medullary osmolality because they act in the renal cortex. Additionally, most loop diuretics have a shorter half-life than thiazides, and patients usually replete the urinary sodium and water losses prior to taking the next dose, thereby minimizing AVP stimulation.[29]

Cerebral (renal) salt wasting syndrome is a condition observed most often in patients with intracranial disorders such as subarachnoid hemorrhage and traumatic brain injury or after neurosurgical procedures, but it can occur in patients without CNS pathology. It results in decreased ECF volume due to a profound natriuresis (urinary sodium loss). A high urine sodium, osmolality, and volume; high serum BUN; orthostatic hypotension; and low central venous pressure suggests cerebral salt wasting.[30] In more severe cases, treatment consists of IV volume repletion with 0.9% NaCl. If serum sodium concentration is less than 120 mEq/L (mmol/L), 3% NaCl may be needed to correct the serum sodium concentration. In some cases, careful titration with 3% NaCl and 0.9% NaCl is required to maintain the serum sodium within an acceptable range.[30] In stable patients, oral administration of a salt supplement and a mineralocorticoid such as fludrocortisone may be used to augment serum sodium and intravascular volume until resolution of this typically transient condition.

Euvolemic Hypotonic Hyponatremia

⑦ Euvolemic (isovolemic) hypotonic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased TBW and ECF volume and is most often caused by SIADH. The increase in ECF volume is not sufficient to cause peripheral or pulmonary edema or other signs of volume overload, and thus patients will appear euvolemic upon physical examination.

In SIADH, water intake exceeds the kidney's capacity to excrete a water load, either because of increased AVP release via non-osmotic and/or nonphysiologic processes or enhanced sensitivity of the kidney to AVP. In most patients with SIADH, the urine osmolality and sodium concentrations will be greater than 100 mOsm/kg (mmol/kg) and 20 to 30 mEq/L (mmol/L), respectively, and serum osmolality will be less than 275 mOsm/kg (mmol/kg) due to ECF volume expansion (see Table 68-2).[4,14]

The most common causes of SIADH are certain cancers (eg, small cell lung, pancreatic, brain), CNS disorders (eg, traumatic brain injury, stroke, meningitis, pituitary surgery), and lung disease (eg, tuberculosis, pneumonia, abscess, acute respiratory distress syndrome). A number of medications can cause SIADH by enhancing AVP release or its action on the kidney or by other mechanisms[13–15,31] (Table 68-3). Patients with kidney and adrenal insufficiency or hypothyroidism can also present with euvolemic hyponatremia. The evaluation of a patient with suspected SIADH should include consideration of these disorders or medications.

TABLE 68-3

Potential Causes of SIADH

Drug-Induced		Nondrug-Induced
Acetaminophen ACE inhibitors Anti-epileptic agents (barbiturates, carbamazepine, lamotrigine, valproic acid) Anti-infectives (linezolid, moxifloxacin) AVP analogs (desmopressin terlipressin, oxytocin, vasopressin,) Bromocriptine Cytotoxic agents (carboplatin, cisplatin, ifosfamide, melphalan, methotrexate, vinca alkaloids)	Chlorpropamide Duloxetine Haloperidol MDMA (ectasy) Monoamine oxidase inhibitors Nicotine NSAIDs Opioids Phenothiazines Proton pump inhibitors Risperidone SSRIs Thioridazine Thiothixene Tolbutamide Tricyclic antidepressants Venlafaxine	Malignancy (lung, pancreatic, duodenal) CNS (trauma, tumor, meningitis, hemorrhage, stroke) Pulmonary (pneumonia, ARDS, TB) Postoperative state Nausea Anxiety

ACE, angiotensin-converting enzyme; ARDS, acute respiratory distress syndrome; AVP, arginine vasopressin; CNS, central nervous system; MDMA, 3,4-methylenedioxymethamphetamin; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone secretion; SSRIs, selective serotonin receptor inhibitors; TB, tuberculosis.

Euvolemic hypotonic hyponatremia may also be caused by primary or psychogenic polydipsia (water intoxication or compulsive water drinking) where more water (usually more than 20 L/day) is ingested than the kidneys can excrete as solute-free water. Unlike in SIADH, AVP secretion is suppressed, resulting in a urine osmolality less than 100 mOsm/kg (mmol/kg). The urine sodium is typically low (less than 15 mEq/L [mmol/L]) due to dilution.[14] Hyponatremia may develop even with more modest water intakes in individuals who ingest low-solute diets.

Hypervolemic Hypotonic Hyponatremia

⑧ Hyponatremia with ECF volume expansion (hypervolemia) occurs in conditions in which both sodium and water excretion are impaired such as HF, cirrhosis, or nephrotic syndrome. These patients have an expanded ECF volume and edema but a decreased effective arterial blood volume. The decrease in the effective circulating blood volume results in renal sodium retention and eventual ECF volume expansion and edema. There is concomitant non-osmotic AVP stimulation and water retention in excess of sodium retention, which perpetuates hyponatremia.

Clinical Presentation

Patients with chronic (longer than 48 hours) mild hyponatremia (serum sodium concentration 125-134 mEq/L [mmol/L]) are usually relatively asymptomatic, with hyponatremia often being discovered incidentally when serum electrolytes are measured for other reasons. Mild symptoms of hyponatremia frequently go unnoticed by both clinicians and patients.[32] Chronic, mild hyponatremia, especially in older adults, has been associated with impairment of attention, posture, and gait; all of which contribute to a substantially increased fall risk.[23–26,33] Even *asymptomatic* patients, when formally tested, have impaired attention and gait to a degree that is comparable to symptoms seen with a blood alcohol level of 0.06% (13 mmol/L).[32]

Patients with moderate (serum sodium concentration 115-124 mEq/L [mmol/L]), severe (serum sodium concentration 110-114 mEq/L [mmol/L]), or rapidly developing hypotonic hyponatremia may present with a range of CNS symptoms resulting from hypoosmolality-induced brain cell swelling. Classic neurologic symptoms include nausea, malaise, headache, lethargy, restlessness, and disorientation. In severe cases, seizures, coma, respiratory arrest, brainstem herniation, and death can occur.

CLINICAL PRESENTATION: Hyponatremia

General

- Severity of symptoms depends on the magnitude and rapidity of onset.
- Too rapid correction can lead to severe neurologic symptoms.

Symptoms

- Symptoms are primarily neurologic in nature.
- Mild: may be asymptomatic; nausea, malaise, gait or cognitive disturbances
- Moderate: headache, lethargy, restlessness, disorientation
- Severe: seizures, coma, respiratory arrest, brainstem herniation, death
- Other symptoms depend on etiology: dry mucous membranes, tachycardia, hypotension, reduced or increased urine output

Laboratory tests

- Serum sodium concentration less than 135 mEq/L (mmol/L)
- Serum osmolality and urine sodium concentration vary depending on etiology
- Altered serum glucose, lipids, proteins, or thyroid function in certain patients

The presence and severity of symptoms depend on both the degree of the hyponatremia and the rate at which it develops. The degree of hyponatremia is important because serum osmolality decreases in direct proportion to the serum sodium concentration, and water movement into cells, including brain cells, increases as serum osmolality decreases. The rate of change of the serum osmolality is important because brain cells are not able to rapidly adjust intracellular osmolality to minimize cellular volume changes.[2,34] When decreased serum osmolality causes water movement into brain cells, inorganic Cl^- and K^+ and organic osmolytes (eg, taurine, glutamate, myoinositol, GABA), move out of the cells to decrease intracellular osmolality and minimize the intracellular water shift. The components of this adaptive mechanism occur and dissipate over different time frames, with Cl^- and K+ efflux occurring and dissipating within minutes to hours and organic osmolyte efflux occurring and dissipating within hours to days.[3,34] Thus, maximal compensation for decreased serum osmolality typically requires up to 48 hours, and acute changes in serum osmolality are more likely to cause symptoms. Gender and age play a role in the response to severe hyponatremia. Young women (pre-menopausal) have been found to have a higher likelihood of death or permanent brain damage compared to men or older women. Female sex hormones may inhibit the Na+/K+-ATPase system. Additionally, interleukin-6 which is found in higher concentrations in women than in men influence vasopressin secretion and reduce the expression of aquaporin-2, impairing free water excretion.[3] Hyponatremia is an important risk factor for morbidity and mortality in patients with HF and cirrhosis.[20,35]

In addition to CNS symptoms, patients with hypovolemic hyponatremia present with signs and symptoms of hypovolemia, including dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, hypotension, and orthostatic hypotension. Lactic acidosis and low mixed venous oxygen saturation, indicating decreased tissue perfusion, may be present with severe hypovolemia.

The brain's adaptation to chronic serum hypoosmolality or hyperosmolality leads to neurologic symptoms when either hyponatremia (hypoosmolality) or hypernatremia (hypertonicity) is corrected too rapidly. The combination of the adaptive decrease in ICF osmolality and a rapid increase in ECF osmolality results in rapid and excessive water movement out of cells, including brain cells, and ICF volume depletion. Thus, too rapid correction of the serum sodium concentration can lead to an acute decrease in brain cell volume, which contributes to the pathogenesis of *osmotic demyelination syndrome* (ODS) or central pontine myelinolysis.[3] While demyelinated lesions identified on magnetic resonance imaging most often occur in the central pons, ODS can extend to other areas of the brain. Patients with ODS may be asymptomatic or develop mild to severe symptoms including confusion, disorientation, dysarthria, dysphagia, hyperreflexia, obtundation, para- or quadriparesis, parkinsonism, pseudobulbar palsy, *locked-in syndrome* (a condition in which a patient is aware and awake but cannot move or communicate verbally due to complete paralysis of nearly all voluntary muscles except for the eyes), seizures, coma, and/or death in 1 to 7 days after correction of the serum sodium concentration.[3,36] If recovery from ODS occurs, it can take several months for symptoms to improve. Patients with significant cerebral adaptation (eg, chronic serum sodium concentration less than 110 mEq/L [mmol/L]) are at highest risk of developing ODS because these patients have a lower intracellular osmolality at the initiation of therapy, and there is a greater decrease in brain cell volume when the serum osmolality is raised too rapidly.[3] Other conditions that increase the risk of ODS include alcoholism, liver disease including orthotopic liver transplantation, potassium depletion, and malnutrition. Thus, if the duration of hyponatremia is unknown, it is generally safer to treat as if it is chronic when developing an initial therapy plan.

Treatment: Hyponatremia

General guidelines for the treatment of patients with hyponatremia are shown in Table 68-4. Application of these principles to the treatment of various forms of hyponatremia is discussed in the following sections.

TABLE 68-4

General Guidelines for Treatment of Hyponatremia

- For both short- and long-term management, treat the underlying cause of hyponatremia, if possible.
- Appropriate treatment of moderate-severe hypotonic hyponatremia requires balancing the risks of hyponatremia vs the risk of ODS.
- Patients who acutely develop moderate-to-severe hyponatremia and/or patients who have severe symptoms are at greatest risk and potentially benefit most from more rapid correction of hyponatremia.
- Correction of hypovolemic hypotonic hyponatremia is usually best accomplished with 0.9% NaCl, as these patients have both sodium and water deficits.
- Active correction of euvolemic and hypervolemic hypotonic hyponatremia in patients who do not require rapid correction is usually best accomplished by water restriction. Demeclocycline, VRA, urea, or a loop diuretic can be used if the initial response to water restriction is not adequate.
- In patients with severe symptoms, 3% NaCl (possibly combined with a loop diuretic) should initially be used to correct the hyponatremia more rapidly. A loop diuretic can be administered concurrently with 3% NaCl to enhance the serum sodium correction by increasing free water excretion.
- Long-term management will be required for patients in whom the underlying cause of hyponatremia cannot be corrected. Depending on the cause, water restriction, increasing sodium intake, and/or a VRA may be used.

NaCl, sodium chloride; ODS, osmotic demyelination syndrome; VRA, vasopressin receptor antagonist.

Desired Outcomes

Regardless of the type or cause of hyponatremia, treatment goals for all patients are to resolve the underlying cause of the sodium and ECF volume imbalance, if possible, and to safely correct the sodium and water derangements. The treatment plan depends on the underlying cause and symptom severity. Patients with acute onset hyponatremia with severe symptoms require more aggressive therapy to correct the hypotonicity. The initial treatment goal is to increase serum tonicity just enough to control severe symptoms which typically requires only a small increase (5%) in the serum sodium concentration. Once severe symptoms have abated, then continued serum sodium correction should be achieved at a slower, more controlled rate. Patients who are asymptomatic or who have only mild to moderate symptoms do not require rapid correction of the serum sodium concentration. While treatment is dictated by the underlying cause, in all cases the goal is to avoid an increase in the serum sodium concentration of more than 6 to 12 mEq/L (mmol/L) in 24 hours (0.5 mEq/L [mmol/L] per hour) or 18 mEq/L (mmol/L) in any 48-hour period.[6,20] When the duration of hyponatremia is unknown, a sodium correction rate of no more than 6 to 8 mEq/L (mmol/L) in 24 hours is prudent to avoid ODS.[3]

ACUTE OR SEVERELY SYMPTOMATIC HYPOTONIC HYPONATREMIA

A patient who has or is at high risk of experiencing severe symptoms caused by hyponatremia (serum sodium less than 110-115 mEq/L [mmol/L]) should receive a small amount of 3% NaCl (513 mEq/L [mmol/L]) until severe symptoms resolve.[2,3] While resolution of severe symptoms generally requires approximately a 5% increase in serum sodium concentration, some clinicians suggest that the initial safe target should be a serum sodium concentration of approximately 120 mEq/L (mmol/L).

The relative concentrations of urine sodium and potassium (osmotically effective urine cations) should be compared with those of the infusate in planning a treatment regimen for patients with hypotonic hyponatremia. For the serum sodium concentration to increase after a NaCl infusion, the sodium concentration of the infusate must exceed the sum of the urinary sodium and potassium concentrations so that an effective net free-water excretion is produced.[6] In SIADH, the urinary concentration of osmotically effective cations often exceeds 154 mEq/L (mmol/L) (sodium concentration of 0.9% NaCl); thus 0.9% NaCl administration could worsen hyponatremia. These patients should be preferentially treated with 3% NaCl.[32,37] The relatively high urinary sodium concentration in patient with SIADH is due to ECF expansion, which minimizes sodium reabsorption along the nephron. When the urine osmolality exceeds 300 mOsm/kg (mmol/kg), it is advisable to administer an IV loop diuretic to increase solute-free water excretion and to prevent volume overload which can result from NaCl administration. Intravenous furosemide 20 to 40 mg given every 6 hours or bumetanide 0.5 to 1 mg given every 2 to 3 hours for several doses is generally sufficient to prevent volume overload and to decrease the urinary concentration of osmotically active cations to less than 150 mEq/L (mmol/L). If intermittent loop diuretic doses are not sufficient to manage volume overload, then either IV furosemide 20 to 40 mg followed by a 10 to 40 mg/hr infusion or IV bumetanide 1 mg followed by a 0.5 to 2 mg/hr infusion can be used.

Patients with hypovolemic hypotonic hyponatremia should be treated initially with 0.9% NaCl. In contrast to SIADH, avid reabsorption of sodium throughout the nephron occurs because the effective circulating blood volume is decreased. Thus, the urine sodium concentration usually will be less than 20 mEq/L (mmol/L), substantially less than the sodium content of 0.9% NaCl. While administration of 3% NaCl will correct hyponatremia, it will not correct the hypovolemia and should be reserved for patients with severe symptoms requiring rapid serum sodium correction.

Acute hypervolemic hypotonic hyponatremia is particularly problematic to manage because the sodium and volume needed to minimize the risk of cerebral edema or seizures can worsen already compromised liver, heart, or kidney function. These patients generally should be treated initially with 3% NaCl and fluid (water) restriction. Loop diuretic or arginine vasopressin receptor antagonist (VRA) therapy is often required to facilitate urinary free water excretion.

Determination of a NaCl Infusion Regimen

Multiple approaches can be used for determining an empiric NaCl infusion regimen for a patient with hyponatremia.[3,7,20] While several complex equations have been published, improved outcomes have not been demonstrated using these equations. Pragmatically, 150 mL[6] or 1 to 2 mL/kg[2] of 3% NaCl can be infused over 20 minutes. If symptoms do not resolve, then 100 mL or 1 mL/kg of 3% NaCl can be administered over 10 to 20 minutes every 30 minutes until symptoms resolve and/or the target serum sodium concentration is reached (usually 5-8 mEq/L [mmol/L] from baseline). Within the first hour, the serum sodium should not increase by more than 5 mEq/L (mmol/L). After relief of symptoms, 0.9% NaCl can be used to continue the sodium correction.

Another method is to calculate the sodium deficit, then replace one-third of the deficit in the first 6 hours and the remaining two-thirds over the following 24 to 48 hours or longer depending on the acuity of the serum sodium decrease. Sodium deficit can be calculated using the following equation:

$$\mathrm{Na_{deficit}\,(mEq\ or\ mmol)=[(Na_D\text{-}Na_s)\times TBW]}$$

Nadeficit(mEq or mmol)=[(NaD-Nas)×TBW]

where Na_D is the goal or desired serum sodium (usually no higher than 120-125 mEq/L [mmol/L] to avoid too rapid or overcorrection); Na_S is the patient's current serum sodium concentration; and TBW is the patient's current TBW calculated as shown in Table 68-5. The change in serum sodium concentration resulting from the infusion of 1 L of 3% NaCl or 0.9% NaCl can be estimated. An example of this approach is shown in Table 68-5.

TABLE 68-5

Assessment and Treatment of Euvolemic Hyponatremia

Change in serum sodium concentration after an IV fluid bolus

$\Delta Na_S = ([Na_{IV} + K_{IV} - Na_S) / (TBW + volume_{IV})$, change in serum sodium concentration; K_{IV}, potassium concentration of infusate; Na_{IV}, sodium concentration of infusate (eg, 154 mEq/L [mmol/L] for 0.9% NaCl; 513 mEq/L [mmol/L] for 3% NaCl); Na_S, initial serum sodium concentration; TBW, total body water (L); and $volume_{IV}$, volume of infused fluid (L)

TBW can be estimated as:

Term newborn infants: 0.7 L/kg × wt (kg); higher in premature infants depending on degree of prematurity

Children and men younger than 70 years: 0.6 L/kg × wt (kg)

Men older than 70 years and women younger than 70 years: 0.5 L/kg × wt (kg)

Women older than 70 years: 0.45 L/kg × wt (kg)

Dehydrated, older patients: 0.4 L/kg × wt (kg)

(Note: wt is the current body weight)

Clinical Example

A 66-year-old man (weight, 70 kg [154 lb]; height, 178 cm [5 ft 10 in.]) presents with nausea, headache, and confusion which developed over the past 3 days. Ten days ago, he began taking carbamazepine for trigeminal neuralgia. His serum sodium concentration on admission to the emergency department was 109 mEq/L (mmol/L). He is diagnosed with drug-induced SIADH.

Plan of Care

1. Discontinue carbamazepine (the likely etiology of his SIADH).
2. Admit to the hospital for correction of hyponatremia.
3. Increase the serum sodium concentration by no more than 6 to 12 mEq/L (mmol/L) during first 24 hours and no higher than 120 mEq/L (mmol/L); thus, the goal is to increase the sodium concentration by 11 mEq/L (mmol/L).
4. Due to degree of hyponatremia (less than 110 mEq/L [mmol/L]) and the presence of moderate-to-severe symptoms, give 3% NaCl.

Calculate the change in serum sodium after 1 L infusion of 3% NaCl:

$\Delta Na_S = (513\text{ mEq/L} - 109\text{ mEq/L})/[(0.5\text{ L/kg} \times 70\text{ kg}) + 1\text{ L}] = 11.2\text{ mEq/L}$ or 1.12 mEq/100 mL

(Note: In SI units, the calculation is the same using mmol/L rather than mEq/L.)

Infusion of 1 L of 3% NaCl will result in a 11.2 mEq/L (mmol/L) rise in the serum sodium concentration. An 11 mEq/L (mmol/L) increase is desired; thus, the appropriate infusion volume is 982 mL [(11 mEq/L/11.2 mEq/L) × 1,000 mL] or [(11 mmol/L/11.2 mmol/L) × 1,000 mL].

(Note: The approach to this calculation would be similar if 0.9% NaCl was used, except that for each 1 L infusion, the expected increase in serum sodium concentration would be only 1.25 mEq/L (mmol/L), and an infusion volume of approximately 8.8 L would be required to achieve the targeted serum sodium concentration.)

5. Moderate-to-severe symptoms: serum sodium concentration should be increased by approximately 1.5 mEq/L/hr (mmol/L/hr) over the first 2 to 4 hours of treatment for a total of 3 to 6 mEq/L [mmol/L] or until the symptoms have resolved. An initial infusion rate of 114 mL/hr for the first 2 to 4 hours is needed.
6. Check serum sodium concentration every 1 to 4 hours depending on rate of rise of serum sodium.
7. Once symptoms subside, continue infusion rate at approximately 23 to 31 mL/hr for the next 20 to 22 hours, to slowly correct hyponatremia. Monitor serum sodium concentration every 4 hours or more often if serum sodium is rapidly changing.

IV, intravenous; SIADH, syndrome of inappropriate antidiuretic hormone secretion; NaCl, sodium chloride

Clinicians may disagree whether or not to administer 3% NaCl to patients with symptomatic hypotonicity. An advantage of 3% NaCl is more rapid correction of serum sodium concentration with a smaller infusion volume. A disadvantage of 3% NaCl is a higher risk of too rapid correction of serum sodium concentration and ODS. Another disadvantage of 3% NaCl is its high osmolality (1026 mOsm/L) which can result in phlebitis and significant tissue damage with extravasation when given via a peripheral IV catheter (~7% complication rate with peripheral administration). Central line administration is preferred but short-term peripheral administration is acceptable if the infusion rate is low and a relatively large peripheral IV catheter is used.[38] The historical use of 5% NaCl has been replaced by 3% NaCl due to these infusion issues. Some clinicians have suggested the use of 2% NaCl to avoid infusion-related issues, but this practice has not been evaluated in clinical trials. Fluid choice depends on the cause and the rapidity of development of the patient's hyponatremia as well as the relative risk of slower correction of the hyponatremia versus the development of ODS.

The appropriate infusion volume for a given patient can be estimated using the amount of fluid needed to provide the calculated sodium deficit or the desired proportion of the estimated change that would result from a 1-L infusion. The final step is to calculate an appropriate infusion rate for the calculated volume that will increase the serum sodium concentration by no more than 6 to 8 mEq/L (mmol/L) in 24 hours in high-risk patients and by 10 to 12 mEq/L (mmol/L) in 24 hours or 18 mEq/L (mmol/L) in 48 hours in others (see Table 68-5).[5] To minimize the risk of too rapid correction of hyponatremia, desmopressin (1-4 mcg) and free water replacement given along with 3% NaCl may be considered in patients with severe hyponatremia until the serum sodium concentration reaches 128 mEq/L (mmol/L).[3,20]

Evaluation of Therapeutic Outcomes

Patients with severely symptomatic hypotonic hyponatremia should be admitted to the ICU or other setting that will allow frequent monitoring of CNS symptoms and volume status. Examination of the heart, lungs, and neurologic status should be performed frequently during the first 12 hours of therapy. The serum sodium concentration should be measured at least every 2 to 4 hours, and the urine sodium, potassium, and osmolality should be measured every 4 to 6 hours during the first 24 to 48 hours of therapy to allow timely infusion rate adjustment to avoid too rapid correction.

NONEMERGENT HYPOVOLEMIC HYPOTONIC HYPONATREMIA

Most patients with hypovolemic hypotonic hyponatremia are either asymptomatic or have only mild-to-moderate symptoms and do not require rapid sodium correction. Many of these patients are at high risk of developing ODS if serum sodium correction occurs too rapidly because they have chronic hyponatremia and maximum compensation by the brain's osmotic adaptive mechanisms. Treatment should include correction of the underlying condition, if possible, and administration of 0.9% NaCl or other isotonic solution (eg, lactated Ringer's, Plasma-Lyte®, Normosol-R®) to correct the hypovolemia. These solutions will replace the existing sodium and water deficits while conveying a lower risk of too rapid sodium correction than 3% NaCl.

The ECF deficit can be estimated based on the patient's sex, age, and change in body weight. One method and an example of its use is shown in Table 68-6. If the patient's previous weight is unknown, the ECF deficit can be roughly estimated based on clinical signs and symptoms. The presence of hyponatremia suggests an ECF deficit of 5% or more, whereas the presence of orthostatic hypotension suggests an ECF deficit of at least 10% to 15%. Administration of an isotonic solution would be optimal to correct the patient's ECF volume deficit because essentially 100% of it will remain in the ECF space (**see** Table 68-1). The overriding initial treatment goal is to restore effective circulating volume; thus, it may be necessary to administer an IV bolus (500-1000 mL in adults; 10-20 mL/kg in children) over a period of 1 hour or less or begin an IV infusion of the isotonic solution at 200 to 400 mL/hr (10-20 mL/kg/hr in children) until symptoms of hypovolemia improve. The infusion rate can then be decreased to 100 to 150 mL/hr (4-6 mL/kg/hr in children) so that the serum sodium concentration does not increase too rapidly. Fluids should be given rapidly enough and in sufficient quantity to restore and maintain adequate tissue perfusion without overloading the cardiovascular or pulmonary system.

TABLE 68-6

Assessment and Treatment of Hypotonic Hypovolemic Hyponatremia

Calculating ECF Deficit

ECF deficit (mL) = $\text{ECF}_{\text{normal}} - \text{ECF}_{\text{current}}$

where ECF volume = 0.33 × TBW

Clinical Example

A 75-year-old woman (height, 168 cm [5 ft 6 in.]; usual weight, 50 kg [110 lb]) was started on hydrochlorothiazide 25 mg once daily 10 days ago for hypertension. She presents with complaints of mild nausea and dizziness when she stands up. Her current weight is 45 kg (99 lb). Upon physical examination she has dry mucous membranes and orthostatic hypotension. Her serum sodium concentration is 126 mEq/L (mmol/L).

Calculate the ECF deficit

ECF deficit = (50 kg × 0.4 L/kg × 0.33) – (45 kg × 0.4 L/kg × 0.33) = 660 mL

(Note: TBW = 0.4 L/kg used because she is a dehydrated older patient; see Table 68-5)

Calculate the expected increase in the serum sodium after infusion of 1 L of 0.9% NaCl (see Table 68-1):

ΔNa_S with 1 L of infusate = [154 mEq/L – 126 mEq/L]/[(0.4 L/kg × 45 kg) + 1 L] = 1.47 mEq/L (mmol/L)

The patient's serum sodium concentration will be 127.5 mEq/L (mmol/L) following the infusion of 1 L 0.9% NaCl

Treatment goals: Restore effective circulating volume and correct serum sodium concentration

Treatment plan:

1. Infuse 0.9% NaCl at 200-250 mL/hr until symptoms of hypovolemia improve; then decrease infusion to 150-200 mL/hr so that the serum sodium concentration increases by no more than 6-12 mEq/L (mmol/L) or 0.5-1 mEq/L/hr (mmol/L/hr) over the initial 24 hours. Rate depends on patient status.
2. Hold thiazide diuretic until volume status is restored.
3. Consider restarting diuretic at lower dose, for example, 12.5 mg once daily, if needed.

ECF, extracellular fluid; NaCl, sodium chloride; TBW, total body water

It is important to recognize that once hypovolemia is corrected, the serum sodium will increase rapidly if the infusion rate is not adjusted appropriately. When the ECF volume is restored, AVP secretion stops, and a rapid water diuresis can ensue, potentially resulting in a rapid increase in serum sodium. Estimating the patient's ECF deficit at the start of therapy may be helpful. If the serum sodium concentration is increasing at a rate greater than 0.5 mEq/L/hr (mmol/L/hr), the infusate can be changed to 0.45% NaCl, and the infusion rate set to slow the rate of serum sodium increase. In general, 0.45% NaCl should not be infused alone as this hypoosmolar solution (154 mOsm/L) may result in red blood cell hemolysis. Most often, Dextrose 5%/0.45% NaCl is infused to provide a relatively isotonic solution (Dextrose 5% provides 250 mOsm/L to the solution). Potassium depletion or repletion can also affect hyponatremia and its correction. One mEq (mmol) of retained potassium equals 1 mEq (mmol) retained sodium; thus, if hypokalemia is corrected at the same time as hyponatremia, the serum sodium may increase more rapidly.

Evaluation of Therapeutic Outcomes

Patients presenting with hypovolemia should be reexamined frequently during the initial few hours of therapy. Of note, the urine output will often lag behind during fluid resuscitation, so careful monitoring for pulmonary congestion is critical, especially in patients with underlying heart, lung, or kidney dysfunction. The serum sodium concentration should be measured every 2 to 4 hours to allow timely adjustment of the rate and composition of IV fluids to avoid too rapidly increasing the serum sodium concentration. In patients with a history of HF or kidney insufficiency, 0.9% NaCl should be administered judiciously with frequent cardiopulmonary assessments so that the infusion rate can be adjusted at the earliest sign of pulmonary congestion.

NONEMERGENT EUVOLEMIC HYPOTONIC HYPONATREMIA

The fact that neurological performance is restored to normal with correction of even mild hyponatremia provides a rationale for maintaining the serum sodium concentration at 130 mEq/L (mmol/L) or higher, if possible. Long-term management will be required for patients in whom the underlying cause is not readily correctable.

Treatment of SIADH always involves restricting water and correcting the underlying cause (see Table 68-2). Medications that could be contributing should be identified and discontinued, if possible. The primary treatment goal is to induce a negative water balance by initially restricting water intake to 1,000 to 1,200 mL/day so that insensible water loss (skin and lung, 900 mL/day) plus obligate urine (500 mL/day) and stool (200 mL/day) loss exceed water intake. Because approximately 850 mL of water per day is ingested in food, and an additional 350 mL are generated from oxidative processes, this degree of water restriction should result in a negative water balance of several hundred milliliters per day. Further water restriction may be needed but adherence is difficult. An additional goal is to maintain the serum sodium concentration close to 130 mEq/L (mmol/L) to reduce CNS symptoms and avoid iatrogenic hypovolemia.

Patients with chronic SIADH who are unable to restrict water intake sufficiently to maintain an acceptable serum sodium concentration can be treated by increasing solute intake with NaCl supplementation and/or loop diuretic administration. NaCl supplements increase the obligatory daily solute excretion, which augments the kidney's capacity for water excretion. The goal is to increase the daily solute intake and excretion to approximately 900 mOsm (mmol) per day. Because an average diet contains approximately 600 mOsm (mmol), 9 g of NaCl would be required to increase the osmolar excretion to 900 mOsm/day (mmol/day). Each 1 g NaCl tablet contains 17 mmol of sodium and 17 mmol of chloride. Because ECF volume expansion is an expected adverse effect, a loop diuretic should be administered concurrently to avoid volume overload and edema. Loop diuretics will also enhance water excretion by limiting the formation of the medullary concentration gradient.

Vasopressin receptor antagonists

VRAs are high-affinity non-peptide antagonists of arginine vasopressin V_2 and V_{1a} receptors, often referred to as *vaptans*.[39] VRAs have dramatic effects on water excretion and were the first significant breakthrough in hyponatremia treatment since loop diuretics. These agents are additional therapeutic options for both euvolemic and hypervolemic hypotonic hyponatremia but are contraindicated in hypovolemic hyponatremia.

Blockade of AVP binding can occur at any of its three distinct receptors: V_{1a}, predominantly in the liver, CNS, and cardiomyocytes; V_2, in the distal nephron; and V_{1b} (formerly V_3), in the anterior pituitary and pancreas.[39] Selective V_2 receptor antagonism prevents AQP2 water channel transport to the apical surface, thereby decreasing AVP-dependent water reabsorption in the collecting duct. AVP inhibition leads to excretion of large water volumes, decreased urine osmolality, and an increase in the serum sodium concentration. These outcomes are achieved without significantly increasing electrolyte excretion; thus, these agents have been called *aquaretics*.

Only two VRAs are currently marketed in the United States, conivaptan and tolvaptan.

Conivaptan (Vaprisol®, Astellas Pharma US, Inc., Northbrook, IL), a mixed vasopressin V_1- and V_2- receptor antagonist, is FDA-labeled for use in the treatment of acute euvolemic and hypervolemic hyponatremia in hospitalized patients. Its utility in chronic hyponatremia is limited because it is only available as an IV formulation, FDA-labeled for up to 4 days of use, a moderate CYP3A4 inhibitor, and not FDA-labeled for use in patients with HF.

Tolvaptan (Samsca®, Otsuka Pharmaceutical Co, Ltd, Tokyo, Japan) is an oral selective VRA with a greater affinity for the V_2 receptor than endogenous AVP. It is FDA-labeled for the treatment of clinically significant (serum sodium concentration less than 125 mEq/L [mmol/L]) euvolemic or hypervolemic hyponatremia or less marked symptomatic hyponatremia that is unresponsive to other therapeutic interventions in patients with HF, cirrhosis, and SIADH. When given alone, tolvaptan promotes aquaresis and modestly raises serum sodium concentrations by 3.6 mEq/L (mmol/L) at 4 days and 4.4 mEq/L (mmol/L) at 30 days, respectively (SALT-1 and SALT-2 studies).[40,41] However, the effect of tolvaptan on serum sodium concentrations may have been limited by the high average fluid intake (~2 L/day) in these studies. In fact, mean increases in serum sodium may be double those found in the SALT studies.[42–44] In SALT-1 and SALT-2, the percentage of patients with a normal serum sodium concentration (greater than 135 mEq/L [mmol/L]) after one month of tolvaptan use was 53% and 58%, respectively, versus 25% (both studies) with placebo.[40,41] When used as monotherapy, tolvaptan is superior to either furosemide or water restriction, and when given in combination with furosemide, there are synergistic effects.[45]

The usual starting tolvaptan dosage is 15 mg given orally once daily based on the SALT studies. A greater risk of overcorrection of serum sodium exists in patients with euvolemic compared to hypervolemic hypotonic hyponatremia.[43,46,47] Thus, a lower starting dosage of 7.5 mg once daily may be considered in patients with euvolemic hypotonic hyponatremia due to its equivalent efficacy and lower risk of overcorrection of serum sodium.[48] This lower dosage should also be used for patients older than 90 years of age.[49]

In critically ill neurological patients, who often require more aggressive care to prevent long-term morbidity, a single tolvaptan dose (7.5 or 15 mg) can effectively increase serum sodium concentration by 5 to 7.8 mEq/L (mmol/L) with the effect sustained for up to 96 hours. Multiple doses may be required. Overcorrection (increasing serum sodium concentration by more than 6 to 12 mEq/L [mmol/L] in 24 hours) may occur, particularly when a 15-mg dose is given, thus careful monitoring in these high-risk patients is warranted.[50,51] Reducing the starting dosage to less than 15 mg/day does not eliminate the risk of too rapid sodium correction.[52]

The oral bioavailability of tolvaptan is about 56%, and its activity peaks at 2 to 4 hours after a dose. For patients who cannot swallow tablets, the tablets can be crushed, suspended in water, and the slurry administered orally or via a nasogastric tube, but a 25% average decrease in the tolvaptan area under the concentration-time curve may be seen with this administration method.[53] Fluid restriction should be avoided within the first 24 to 48 hours of starting VRA therapy when active sodium correction is occurring.[20] After 24 hours, if a greater increase in serum sodium concentration is needed, the dosage may be increased to 30 mg once daily, and after another 24 hours, to a maximum of 60 mg once daily.

Approximately 10% to 50% of patients do not significantly respond to VRA therapy.[54,55] Therapeutic resistance or failure to respond to VRA therapy could be due to high circulating AVP concentrations, AVP-independent impaired urinary dilution, excessive water intake, or an activating V_2-receptor mutation causing nephrogenic SIADH.[39] There is currently no pharmacogenomic information available for the G protein-coupled receptor family of AVP receptors or the VRAs that can be used to individualize therapy.[56]

Tolvaptan is primarily metabolized to inactive metabolites by CYP3A4 and less than 1% is eliminated unchanged in the urine; thus, its use should be avoided in patient’s receiving potent CYP3A4 inhibitors (eg, ketoconazole, clarithromycin, itraconazole, ritonavir). Concomitant therapy with P-glycoprotein inhibitors and grapefruit juice results in increased serum tolvaptan concentrations. Tolvaptan inhibits P-glycoprotein and coadministration with P-glycoprotein substrates should be avoided, if possible.[57] Conversely, optimal tolvaptan benefits may not be achieved on usual dosages in patients who are receiving potent CYP3A4 inducers (eg, phenytoin, phenobarbital, St. John’s Wort).

Tolvaptan therapy is contraindicated in patients needing rapid serum sodium correction (due to the 2- to 4-hour delayed onset), those unable to sense or respond appropriately to thirst, patients with hypovolemic hyponatremia, patients taking strong CYP3A4 inhibitors, and patients who are anuric. Tolvaptan has not been studied in patients with severe hyponatremia (severe symptoms or serum sodium less than 120 mEq/L [mmol/L]). Patients with more profound hyponatremia are more likely to experience larger increases in serum sodium concentrations. Tolvaptan should be used cautiously in these patients with serum sodium concentration monitoring every 2 to 4 hours.

Tolvaptan effectively produces aquaresis and increases serum sodium concentrations in patients with chronic kidney disease (CKD stages 3, 4, 5) who are not receiving renal replacement therapy.[58,59] VRA use should be avoided with hypertonic saline (eg, 3% NaCl) due to the risk of too rapid and/or overcorrection of the serum sodium concentration. Thirst, dry mouth, weakness, constipation, hyperglycemia, and urinary frequency are the most common adverse medication reactions, and they rarely necessitate therapy discontinuation.[40,41]

Reversible increases in hepatic transaminases have been reported with tolvaptan use; however, concerns for irreversible liver damage arose in the TEMPO 3:4 trial which evaluated tolvaptan in patients with autosomal dominant polycystic kidney disease. Tolvaptan dosages (45-120 mg/day) were much higher than those typically used for hyponatremia, and the duration of therapy was longer than 30 days (up to 3 years in some patients). Increases in hepatic transaminases did not meet Hi’s criteria for medication-induced liver injury because the total bilirubin was not elevated to more than twice the upper limit of normal.[60] The FDA has issued a warning to avoid tolvaptan use for more than 30 days in anyone with chronic liver disease. Additionally, tolvaptan should be discontinued if any sign of liver injury occurs during therapy. To reduce the ODS risk, tolvaptan therapy should begin or resume only in a hospital where the serum sodium concentration can be closely monitored (boxed warning).

VRAs are more expensive than other treatment options. Multiple economic analyses have determined tolvaptan therapy to be cost-effective for SIADH and HF when compared to fluid restriction or no additional therapy as evidenced by reduced hospital stay, avoidance of ICU admission, and avoidance of hospital readmission.[61–63] However, the cost-effectiveness of VRAs in the management of patients with SIADH is still unclear when considering all therapeutic modalities. Therapy continuation after acute treatment depends on the etiology of SIADH. While many cases are transient, other etiologies require indefinite treatment. The inability to discontinue the offending agent in medication-induced SIADH may also necessitate long-term treatment.

When considering long-term VRA treatment, cost and potential liver toxicity must be weighed against potential benefits.

It is unclear whether improving or normalizing the serum sodium concentration improves the morbidity and/or mortality associated with hyponatremia. Additional research is needed to compare VRA use with traditional therapies after fluid restriction in the acute phase of nonemergent euvolemic hyponatremia. Further investigation is also warranted for long-term VRA use in asymptomatic or minimally symptomatic hyponatremia, particularly in older adults, to reduce morbidity (eg, cognitive deficits, gait disturbance, falls, bone fractures).

Sodium-Glucose Co-Transporter-2 Inhibitors

Sodium-glucose co-transporter-2 (SGLT2) inhibitors are oral hypoglycemic medications with cardiovascular and kidney benefits. Through blockade of SGLT2, a glucose transporter in the proximal renal tubule responsible for 90% of glucose reabsorption, SGLT2 inhibitors lead to excretion of 50% to 60% of filtered glucose, approximately 60 to 100 g/day. The resulting glucosuric effect causes an osmotic diuresis and increases free water excretion.[64] The use of SGLT2 inhibitors in addition to standard fluid restriction of less than 1,000 mL/day in patients with euvolemic hypotonic hyponatremia results in an increased median plasma sodium concentration compared to placebo (10 vs 7 mEq/L [mmol/L]), but this difference may not be clinically significant.[65] Further studies are needed before SGLT2 inhibitors can be routinely recommended for treatment of euvolemic hypotonic hyponatremia.

Demeclocycline

Demeclocycline, a semisynthetic tetracycline antibiotic, is a treatment option for some patients with SIADH whose serum sodium concentration is not adequately controlled by water restriction alone. Demeclocycline use in SIADH is largely based on clinical experience rather than data from clinical trials and it is ineffective in a significant proportion of patients.[4,66] Demeclocycline essentially causes nephrogenic diabetes insipidus (DI) by unpredictably inhibiting tubular AVP activity, which increases free water excretion. Some patients may even develop polyuria and hypernatremia due to this mechanism. The demeclocycline dosage is 300 mg given orally two to four times daily. Because of the delayed onset of action (2-6 days), this agent has no role in the acute management of severe hyponatremia, and dosage adjustments should be made no more frequently than every 3 to 4 days. Demeclocycline should not be used in patients with cirrhosis or compromised fluid intake, who are at high risk for demeclocycline-induced renal tubular toxicity and acute kidney failure[4], who are pregnant, or who are younger than 8 years unless no other options are available because long-term use may interfere with tooth and bone development. Photosensitivity with skin rash may occur; thus, patients receiving demeclocycline should be counselled to use appropriate UV protection during sun exposure.

Urea

Urea is an osmotic agent that increases urinary free water excretion and decreases urinary sodium excretion. Urea has been used as an alternative oral for treatment for SIADH and other hyponatremic disorders. The administration of urea at a dose ranging from 7.5 to 90 g/day for a median of 4.5 days in the inpatient setting[67] and 15 to 30 g/day for up to 1 year in the outpatient setting[68] is safe and effective for treatment of hyponatremia. Adherence to therapy is a concern due to the bitter taste of urea. The FDA considers urea to be a medical food, thus a prescription is not required. An over-the-counter product, ure-Na™ (Nephcentric LLC, Phoenix, AZ) is available that provides 15 g powder in a packet that can be dissolved in water or juice (juice usually preferred due to taste). While there is little quality evidence for the efficacy of urea in the treatment of SIADH or other hyponatremic disorders, it is recommended as a second-line agent in the European guidelines.[6]

Evaluation of Therapeutic Outcomes

The serum sodium concentration should be monitored at least every 4 to 6 hours during the active sodium correction phase with treatment other than fluid restriction until reaching a stable value greater than 125 mEq/L (mmol/L). The serum sodium concentration should be measured every 24 to 48 hours when water restriction is initiated until it stabilizes at a concentration at or above 125 mEq/L (mmol/L).[20] Continued decline in the serum sodium concentration would indicate either nonadherence to the prescribed water restriction or the need for more aggressive restriction. If tolvaptan is initiated, the serum sodium concentration should be monitored every 4 to 8 hours for the first 24 to 48 hours.[20]

When the serum sodium has increased by 6 to 8 mEq/L (mmol/L), oral water or IV Dextrose 5% in water (D_5W) should be given to replace urine output to minimize the risk of overcorrecting the serum sodium concentration and ODS. Variable reported rates of sodium overcorrection may be due to differences in baseline serum sodium and definitions of excessive correction. In the SALT trials, only 1.8% of patients exceeded the daily limit for changes in serum sodium; however, most had serum sodium concentrations greater than 130 mEq/L (mmol/L) at the start of treatment and were protected from overcorrection by thirst, so the risk of sodium overcorrection in clinical practice may be greater.[40,41] In a Cochrane review, VRA therapy increased the risk of a rapid increase in serum sodium (greater than 8 mEq/L [mmol/L] in 24 hours) by 67%, with an additional three patients per 100 treated with a VRA experiencing a rapid sodium increase versus placebo.[69] Other studies have shown a ~25% incidence among patients with euvolemic hypotonic hyponatremia. In these studies, patients with profound hyponatremia (baseline serum sodium 121 mEq/L [mmol/L] or less) experienced significantly greater rates of increase; although none developed neurological symptoms or ODS.[42,47] Since 2010, 38 cases of ODS including five deaths have been reported through the FDA Adverse Events Reporting System (FAERS; fis.fda.gov). Once the serum sodium concentration is stable at 125 mEq/L (mmol/L) or higher, the patient should be evaluated every 2 to 4 weeks to assess neurologic status and to obtain serum and urine sodium, potassium, and osmolality values. Volume status assessments (eg, BP, mucous membranes, skin turgor, heart, and lung examination) should also be done, particularly in patients who are being treated with NaCl supplements and/or loop diuretics.

NONEMERGENT HYPERVOLEMIC HYPOTONIC HYPONATREMIA

The initial treatment goals for patients with asymptomatic or minimally symptomatic hypervolemic (expanded ECF volume) hypotonic hyponatremia include achieving a negative water balance and minimizing rapid changes in brain cell volume until the serum sodium concentration is 125 mEq/L (mmol/L) or higher. Management involves correction of the underlying cause, when possible, as well as water restriction of 1,000 to 1,500 mL/day.[35] To be effective, the combined daily losses (insensible water, urine, and stool) must exceed fluid intake. Additionally, dietary sodium intake should be restricted to 1,000 to 2,000 mg/day, depending on the degree of ECF volume expansion. On average, only modest changes in serum sodium concentration are seen over the first 5 days of treatment with fluid restriction (2 mEq/L [mmol/L; IQR 0-4] at 24 hours[70,71]; 0.7 ± 2.1 mEq/L [mmol/L] on day 5.[72] This small change may be due to poor adherence to fluid restriction and the frequent patient practice of sucking on ice chips to quench thirst. In moderately severe cases, other options should be considered if serum sodium does not improve in the first 24 to 48 hours.

In patients with HF, the severity of hypervolemic hypotonic hyponatremia is directly related to HF severity and is associated with a poorer short- and long-term prognosis once the serum sodium concentration falls below 137 mEq/L (mmol/L).[73,74] Patients with hypervolemic hypotonic hyponatremia caused by HF should be treated with measures that can potentially improve cardiac contractility and effective circulating volume, thereby limiting non-osmotic AVP release. Therapeutic options include digitalis or afterload reduction with angiotensin-converting enzyme inhibitors (ACEI), angiotensin II receptor blockers (ARB), or angiotensin receptor-neprilysin inhibitors (ARNI). Of these, only ACEI provide benefit in partially correcting hyponatremia in patients with HF[75]; however, sodium correction with ACEI does not improve outcomes.[76] No specific ACEI offers any particular advantage for this indication, and the dosage should be titrated to keep the systolic BP between 100 and 130 mm Hg. Dose-limiting adverse medication reactions of ACEI include hyperkalemia (serum potassium concentration greater than 5.5 mEq/L [mmol/L]) and impaired kidney function. The benefits and risks of continuing ACEI use must be weighed carefully in each case, but a decrease in glomerular filtration rate (GFR) of less than 30% that stabilizes within 2 months of beginning ACEI therapy generally does not require dosage reduction or discontinuation.[73]

Other potentially treatable causes of asymptomatic hypervolemic hyponatremia include nephrotic syndrome and cirrhosis. An ACEI can be used to decrease proteinuria in patients with nephrotic syndrome, leading to partial correction of hypoalbuminemia and to a decrease in non-osmotic AVP release. Management of asymptomatic cases of hyponatremia in patients with cirrhosis includes temporary discontinuation of diuretics and cautious correction of hypokalemia in addition to fluid restriction.[35] Exogenously administered potassium will enter the cells as intracellular sodium is exchanged in the opposite direction. This increase in extracellular sodium must be accounted for to avoid rapid overcorrection of hyponatremia. If hyponatremia persists in patients with cirrhosis, short-term hyper-oncotic albumin solutions (20%-25%) may be administered at dosages of at least 40 g/day.[77,78] Efficacy is likely due to increased urinary free water clearance following intravascular volume expansion.[35]

VRAs have also been used for the treatment of hypervolemic hypotonic hyponatremia in patients with HF or cirrhosis.[79–84] Conivaptan is not an ideal choice for patients with cirrhosis due to its mixed antagonism of the V_1 and V_2 receptors. V_1 receptor blockade in these patients may worsen hypotension, increase bleeding risk, and compromise kidney function.[80] As previously mentioned, the FDA issued a warning regarding tolvaptan use in patients with impaired liver function due to the potential for further liver injury. However, 25% and 31% of patients in the tolvaptan groups of the SALT-1 and SALT-2 trials, respectively, had underlying liver cirrhosis, and there were no cases of further liver injury.[40,41] Subsequent studies have supported these findings.[81,82] The optimal tolvaptan starting dosage in patients with cirrhosis is unknown. Given the concern for hepatotoxicity, a dose of 3.75 or

7.5 mg may be appropriate; however, usual starting dosages may be recommended based on the SALTWATER study.[35,83,85]

Patients with cirrhosis who receive tolvaptan generally have a more modest increase in serum sodium concentrations compared to patients with euvolemic hyponatremia, and the increase may be more dependent on baseline GFR.[82–85] Patients with advanced cirrhosis may benefit from placement of a transjugular intrahepatic portosystemic shunt, which can increase the effective circulating volume and thus reduce non-osmotic AVP release.[86] This procedure can potentially exacerbate or precipitate hepatic encephalopathy and is not recommended in patients with a history of encephalopathy. Additionally, tolvaptan may be considered in patients with end-stage liver disease awaiting liver transplantation to normalize serum sodium concentrations.[35,87] The benefit of avoiding the need for rapid perioperative sodium correction outweighs the likely negligible effect of tolvaptan-related liver damage in these patients. It is also reasonable to continue treatment until liver transplantation even if the duration is longer than 30 days.

In general, VRA treatment in hyponatremic patients with HF is reserved for refractory patients whose hyponatremia does not adequately respond to other medical management strategies. Tolvaptan dosing for HF-associated hypervolemic hyponatremia is the same as for euvolemic hypotonic hyponatremia. In the short-term management of patients with HF with hypervolemic hyponatremia, tolvaptan use decreases body weight, increases urine output, decreases left ventricular filling pressures, and decreases urine osmolality; however, evidence for clinical benefits such as improved dyspnea is lacking.[88–94] Long-term beneficial effects, reduction in hospitalization or death, or slowed HF progression have not been observed in several pivotal trials. A post-hoc analysis of the EVEREST trial, however, showed patients with severe hyponatremia (less than 130 mEq/L [mmol/L]), who presumably had greater activation of the arginine-vasopressin axis, had reduced cardiovascular morbidity and mortality after discharge.[94] Prolonged tolvaptan use leads to an increased endogenous AVP concentration, and this overstimulation of V_{1a} receptors can lead to increased afterload and HF progression.[95] However, no worsening of left ventricular dilatation was observed after 52 weeks of tolvaptan therapy (30 mg/day).[96] In contrast to European guidelines, an American expert panel on hyponatremia recommended a VRA in non-severe hyponatremia when fluid restriction is unsuccessful.[20] The 2013 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) guidelines recommend short-term use of a VRA in hospitalized patients who have volume overload and persistent severe hyponatremia and who are at risk for or having cognitive symptoms despite fluid restriction and optimization of guideline-directed medical therapy.[97] It is still unknown whether VRAs decrease length of hospitalization, rehospitalization rates, or morbidity or increase quality of life when compared to other treatments.

Various biological markers, such as copeptin, the c-terminal segment of the precursor of provasopressin; apelin; and midregional proatrial natriuretic peptide (MR-proANP), may have diagnostic utility for hyponatremia in HF and improve the overall management.[98] The association between copeptin peptide concentrations and tolvaptan response was investigated in patients with HF and may help determine the most appropriate patients for VRA use.[99] Given the potential vascular and cardiac effects of V_{1a} receptor stimulation and V_{1a} receptor dose-dependent activity (as opposed to maximal V_2 signaling at low AVP activity levels), an oral V_{1a} or nonselective VRA likely would provide greater benefits in patients with HF.[100]

Evaluation of Therapeutic Outcomes

Patients being treated for hypervolemic hyponatremia should initially be evaluated on a daily basis for lung congestion, ascites, peripheral edema, and signs or symptoms of hyponatremia. If water restriction is started, the serum sodium concentration should be measured daily until it stabilizes at 125 mEq/L (mmol/L) or higher. If VRA therapy is initiated, serum sodium concentrations should be monitored every 4 hours to minimize the risk of overcorrection and ODS. Patients should be assessed 1 week following discharge, and then every 2 to 4 weeks to assess adherence to water restriction and other therapies, volume status, and symptoms.

HYPERNATREMIA

Epidemiology and Etiology

⑩ Hypernatremia, defined as a serum sodium concentration greater than 145 mEq/L (mmol/L), is always associated with hypertonicity and intracellular dehydration, resulting from a water deficit relative to ECF sodium content. This hypertonic state is a potent stimulus for AVP secretion and thirst. Therefore, hypernatremia is most commonly observed in patients with an impaired thirst response or in those who cannot access water. Young infants and children, mechanically ventilated or comatose patients, older adults, and patients with an impaired sensorium or functional status are at highest risk for this disorder.[101] Hypernatremia generally occurs in sicker patients and has a higher mortality.[102] The incidence of hypernatremia in general medical–surgical hospitalized patients and patients in ICUs has been estimated to be at least 1% and as high as 26% to 59%, respectively.[103–107] A marked increase in the incidence of hypernatremia compared to hyponatremia has occurred in ICUs in the past two decades. In critically ill patients, the majority of cases of hypernatremia are iatrogenic, the result of too little free water and too much hypertonic solution along with increased renal water loss.[108] Focusing only on overall fluid balance and not considering the sodium intake from all sources, including excessive isotonic fluids, and evaluating urine sodium excretion leads to hypernatremia, and more free water is needed in most cases.[106,109]

Clinical outcomes in patients with hypernatremia, as in hyponatremia, depend on the severity of the increase and the rapidity with which it develops. In children, mortality from acute hypernatremia developing in less than 72 hours ranges from 10% to 70%; while chronic hypernatremia which develops over 3 or more days has a mortality rate of only 10%.[110] In adults, an acute increase in serum sodium concentration to greater than 160 mEq/L (mmol/L) is associated with a 75% mortality rate, and hypernatremia that develops at a slower rate also has a high mortality rate of approximately 60%.[111] Hypernatremia is often associated with a serious underlying illness, which likely contributes to the higher mortality rate.

Pathophysiology

Hypernatremia most often results from water loss by either renal or extrarenal mechanisms. Hypernatremia also results from hypertonic or isotonic fluid administration or excess sodium ingestion. Patients can develop hypovolemic, hypervolemic, or euvolemic (isovolemic) hypernatremia depending on the relative magnitude of sodium and water loss or gain caused by the underlying condition (Table 68-7).

TABLE 68-7

Characteristics of Hypernatremic States

Characteristics	Hypovolemic Hypernatremia	Euvolemic (Isovolemic) Hypernatremia	Hypervolemic Hypernatremia
Water and sodium	Water loss >> sodium loss	Water loss only	Sodium gain > water gain
Causes	Renal: osmotic diuresis, diuretic use, postoperative diuresis, high-output acute tubular necrosis	Congenital or acquired DI Nephrogenic DI Primary polydipsia	Sodium overload (eg, 3% NaCl, sodium bicarbonate, NaCl tablets, concentrated tube feedings, hypertonic dialysate, sodium-containing medications)
Effect on TBW	↓↓	↓	↑
Effect on TBNa	↓	↔	↑↑
Additional laboratory findings	Renal: UOsm high, UNa high Non-renal: UOsm high, UNa low	Renal: UOsm low, UNa variable Non-renal: UOsm high, UNa variable	UOsm high, UNa high
Clinical presentation	Orthostasis, hypotension, tachycardia, dry mucous membranes	Depends on severity of hypernatremia; seizures, lethargy	Peripheral and pulmonary edema, variable BP
Treatment	0.9% NaCl until vital signs stable, then free water replacement	Free water replacement, AVP, or AVP analogue	Free water replacement with loop diuretic, may require hemodialysis to remove volume

AVP, arginine vasopressin; DI, diabetes insipidus; NaCl, sodium chloride; TBNa, total body sodium; TBW, total body weight; UNa, urine sodium concentration; UOsm, urine osmolality

Water loss commonly occurs as a result of insensible losses (evaporative water loss through the skin and lungs) in patients deprived of water. Hospitalized patients who are febrile or being mechanically ventilated are often treated with isotonic IV fluids which contain insufficient free water to replace insensible losses. Hypernatremia can develop in patients with hypotonic GI losses (eg, diarrhea, vomiting, gastric suctioning) or in patients who have been exposed to high temperatures who suffer large water losses from both sweat and insensible losses.

A water diuresis can be caused by DI, which can be classified as either central DI (decreased AVP secretion) or nephrogenic DI (decreased kidney response to AVP). Patients with untreated DI excrete large volumes (3-20 L/day) of dilute urine, resulting in hypernatremia. Various causes of DI are listed in Table 68-8. Lithium, which impairs AVP-mediated water transport, is the most common cause of acquired nephrogenic DI.[112]

TABLE 68-8

Causes of DI

Central	Nephrogenic	Other
Familial[a] Unreplaced insensible losses Skin Lung Hypodipsia Neurogenic Neurosurgery Tuberculosis Head trauma CNS malignancy/cyst Ethanol ingestion (transient) Hypoxic encephalopathy Lung tumor Sarcoidosis Sheehan syndrome[b]	Familial Inherited aquaporin-2 defect Inherited vasopressin V2 receptor defect Hypercalcemia (chronic) Hypokalemia Kidney disease Medication-induced **Most common** Lithium – most common Foscarnet Clozapine **Less common** Amphotericin B Cidofovir Didanosine Ifosfamide Orlistat Vasopressin receptor antagonists	Gestational Primary polydipsia (dipsogenic DI)

AVP, arginine vasopressin; CNS, central nervous system; DI, diabetes insipidus.

[a] At least 60 mutations in the AVP gene cause neurohypophyseal DI.

[b] Postpartum hypopituitarism caused by severe bleeding during childbirth.

Hypertonic NaCl administration can result in hypervolemic (expanded ECF volume) hypernatremia. This type of hypernatremia is typically iatrogenic following excess sodium bicarbonate administration, hypertonic NaCl enemas, or intrauterine injection of hypertonic NaCl. Excessive isotonic infusions (0.9% NaCl, lactated Ringers; see Table 68-1) may lead to sodium accumulation, particularly when dilute urine is excreted. A common cause of hypernatremia in the ICU is sodium intake from IV and enteral fluids and medications.[102,105-113] Sodium balance should be monitored carefully in critically ill patients to avoid iatrogenic hypernatremia. Patients with hyperaldosteronism also may present with an expanded ECF and mild hypernatremia.

Clinical Presentation

Hypernatremia results in water movement from the ICF to the ECF. Patients with central DI often present with sudden onset of polyuria, whereas patients with nephrogenic DI develop polyuria more gradually. Symptoms are like those seen with hyponatremia and are primarily neurological due to decreased brain cell volume. Symptoms of mild-to-moderate hypernatremia (hypertonicity) include weakness, lethargy, restlessness, irritability, twitching, and confusion. More severe or rapidly developing hypernatremia can lead to seizures, coma, and death. As discussed in the hyponatremia section, brain cells adapt to ECF tonicity changes by decreasing or increasing the concentration of inorganic (K^+, Cl^-) and organic (glutamate, taurine, and myoinositol) osmolytes.[2,34] ECF hypertonicity results in intracellular organic osmolyte generation within 24 hours of onset leading to an increase in ICF tonicity that then draws water into brain cells, limiting the decrease in cell volume. Thus, patients with chronic hypernatremia are less likely to be symptomatic than patients with acute hypernatremia.

CLINICAL PRESENTATION: Hypernatremia

General

- Increased serum sodium concentration and osmolality causes acute water movement from the ICF to the ECF.
- Decreased brain cell volume can cause cerebral vein rupture, leading to focal intracerebral and subarachnoid hemorrhages and irreversible CNS damage.

Symptoms

- Mild: lethargy, weakness, confusion, restlessness, irritability
- Moderate: twitching
- Severe: seizures, coma, death; usually requires acute increase in serum sodium to ≥160 mEq/L (mmol/L)
- Serum sodium ≥180 mEq/L (mmol/L) is associated with high mortality
- Other symptoms (depend on etiology of hypernatremia): postural hypotension, tachycardia, dry mucous membranes, diminished skin turgor, reduced or increased urine output
- Signs and symptoms are difficult to detect in patients with underlying neurologic dysfunction.

Laboratory tests

- Serum sodium concentration greater than 145 mEq/L (mmol/L)
- Serum osmolality is always high.
- Urine osmolality may be helpful in diagnosing the cause.

Hypernatremia is often associated with serious underlying illness, and signs and symptoms related to the illness are often present. Patients with a history of severe diarrhea or vomiting can present with ECF volume depletion. Older patients deprived of water after sustaining a stroke or hip fracture often present with mental status changes and other signs of ECF volume depletion. Clinically detectable ECF volume depletion, however, may not be evident until the serum sodium concentration exceeds 160 mEq/L (mmol/L) because these patients primarily have water loss, two-thirds of which is derived from the ICF. The urine will be concentrated, often exceeding 450 mOsm/kg (mmol/kg), because of osmotic and non-osmotic AVP release. The first step in the evaluation and treatment of hypernatremia is assessment of the ECF and urine volume and the serum and urine osmolality (Fig. 68-3).

Patients with a contracted ECF volume and low urine output include those who have sustained insensible water losses that exceed intake, as well as those with extrarenal losses of hypotonic fluids. On physical examination, the patient will have postural hypotension, diminished skin turgor, and delayed capillary refill. Lactic acidosis and low mixed venous oxygen saturation, indicating decreased tissue perfusion, may be present. The daily urine output is typically less than 1 L.

In older adults, hypotension, tachycardia, dry oral mucosa, decreased skin turgor, and recent changes in consciousness are all more common in patients with hypernatremia. The presence of signs of dehydration are variable, with orthostatic hypotension and decreased subclavicular and forearm skin turgor present in at least 60% of patients.[114]

Osmotic Diuresis

In the presence of an ongoing osmotic diuresis, patients will have a urine volume greater than 3 L/day. Excessive urinary excretion of glucose, sodium, urea, or an exogenously administered solute (eg, mannitol) can be identified either by history or by direct measurement of serum and urinary concentrations of the suspected solute, if possible. Patients with post-obstructive diuresis, such as those with bladder outlet obstruction caused by prostatic hypertrophy, are usually ECF volume expanded because of retained solute because of a reduction in GFR. The osmotic diuresis that follows resolution of the obstruction is appropriate in that it promotes excretion of the excess solute.

Patients with severe hyperglycemia may have a low measured serum sodium concentration (hyponatremia) but a high *corrected* sodium concentration (hypernatremia). Patients with severe hyperglycemia present with signs of hypovolemia, and the diuresis is inappropriate as it further exacerbates the ECF volume contraction associated with hyperglycemia. As previously discussed, the estimated (or corrected) serum sodium concentration can be calculated by adding 1.6 mEq/L (mmol/L) for every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration before estimating the water deficit.[5,28]

Diabetes Insipidus

Patients with DI tend to maintain a normal ECF volume if they are conscious, can drink, and have access to water. Patients typically have only a slight increase in the serum sodium concentration (usually 141-145 mEq/L [mmol/L]), and a daily urine volume greater than 3 L.

A water deprivation test has been recommended to aid in the differential diagnosis. This diagnostic test consists of depriving a patient with marked polyuria of water for 8 to 12 hours in a supervised setting to avoid severe hypernatremia and volume depletion. Body weight and urine osmolality and volume are measured before and after administration of desmopressin acetate (4 mcg subcutaneously or intravenously or 10 mcg intranasally). After desmopressin administration, patients with central DI will have a prompt increase in urine osmolality to approximately 600 mOsm/kg (mmol/kg) and decreased urine volume. In patients with nephrogenic DI, the urine osmolality will not increase above 300 mOsm/kg (mmol/kg).[115]

The value of a water deprivation test in patients with polyuria and hypernatremia has been questioned. Because hypernatremia provides a maximal stimulus for AVP secretion, discriminating between nephrogenic and central DI can be based on the serum AVP concentration and urinary response to desmopressin without the need for a water deprivation test. The water deprivation test is likely to be of diagnostic value only in patients with polyuria and a normal serum sodium concentration.[116]

Sodium Overload

Patients who have ingested a large amount of sodium (more than four tablespoons table salt [1,400 mEq or mmol sodium]) or who have received more than 5 L of hypertonic fluids are volume expanded; although, this volume may not always be clinically evident as edema. Volume expansion results in an osmotic diuresis, polyuria, and a urine osmolality greater than 300 mOsm/kg (mmol/kg). In patients with normal perfusion and kidney function, the excess sodium will be excreted in the urine; with organ dysfunction, sodium excretion is compromised, and volume expansion occurs.

Treatment

Desired Outcomes

Treatment goals for patients with hypernatremia include correcting the serum sodium concentration to between 145 and 150 mEq/L (mmol/L) at a rate that restores and maintains brain cell volume as close to normal as possible while normalizing ECF volume, if indicated. Hypernatremia is often undertreated; adequate treatment should result in symptom resolution. Although inadvertent overcorrection is more common with hyponatremia, careful titration of fluids and medications should minimize the adverse effects associated with too rapid correction of hypernatremia, including cerebral edema, seizures, neurologic damage, and death. These complications occur almost exclusively in young children with chronic hypernatremia (at least 48 hours duration) and serum sodium concentrations greater than 150 mEq/L (mmol/L).[2] Water replacement and dietary sodium restriction can be necessary to prevent recurrence of hypernatremia.

Physical examination with attention to volume status and laboratory measurement of serum and urine sodium and osmolality should be completed every 2 to 3 months during chronic therapy. A 24-hour urine collection to measure urine volume and sodium excretion may help guide diuretic therapy and determine adherence to sodium restriction.

Hypovolemic Hypernatremia

Patients with symptomatic hypovolemic hypernatremia should be treated similarly to those with hypovolemic hyponatremia with 0.9% NaCl or another isotonic fluid until hemodynamic stability is restored (Fig. 68-3). An initial infusion rate of 200 to 300 mL/hr or higher will likely be appropriate for most adults; children generally receive 10 to 20 mL/kg/hr. Once intravascular volume is restored, 0.45% NaCl, D_5W, or another hypotonic fluid, may be infused to correct the water deficit. In patients with hypernatremia from water loss, the ECF volume deficit can be estimated as follows:

$$\mathrm{ECF(water)deficit} = \mathrm{TBW}_{\mathrm{current}} \times [1 - (140/\mathrm{Na_s})]$$

ECF(water)deficit=TBWcurrent×[1-(140/Nas)]

where Na_S is the initial serum sodium concentration (in mEq/L [mmol/L]), and 140 is the normal or goal serum sodium concentration in mEq/L (mmol/L). Although this formula provides an estimate of the water deficit caused by pure free water loss, it underestimates the deficit in patients with hypotonic fluid loss.[2]

The appropriate rate for correcting the water deficit depends on the rapidity with which the hypernatremia developed. Hypernatremia developing in less than 48 hours can be initially corrected at a rate of approximately 1 mEq/L (mmol/L) per hour, whereas a rate of 0.5 mEq/L (mmol/L) per hour or less should be used when hypernatremia has developed more slowly.[2,112] The sodium should be lowered no more than 10 to 12 mEq/L (mmol/L) per day.[2] Renal replacement therapy may be needed for patients with kidney failure; NaCl will be added to the replacement fluid/dialysate to achieve the same sodium content as the goal serum sodium concentration to avoid too rapid overcorrection and cerebral edema.[102]

The serum sodium concentration and volume status should be monitored every 2 to 3 hours during the first 24 hours of treatment in patients with symptomatic hypernatremia to permit appropriate adjustment of the rate of the hypotonic fluid administration. Once symptoms resolve and the serum sodium concentration is less than 148 mEq/L (mmol/L), measuring serum sodium concentrations every 6 to 12 hours and assessing fluid status every 8 to 24 hours is generally adequate.

Recurrent iatrogenic hypernatremia can be prevented by avoiding infusing excessive hypertonic solution, providing adequate *maintenance* fluids, and replacing ongoing abnormal losses. Traditional maintenance fluid for adults and children weighing 40 kg or more is Dextrose 5%/0.45% NaCl with 20 mEq (mmol) KCl/L. Children weighing less than 40 kg typically receive Dextrose 5%/0.2% NaCl with 20 mEq (mmol) KCl/L, except infants younger than 3 months who may receive Dextrose 10%/0.2% NaCl with 20 mEq (mmol) KCl/L. These fluids were chosen to provide a small amount of glucose for CNS function and to replace usual urinary sodium and potassium losses. Estimating daily fluid requirements and calculation of an appropriate maintenance fluid rate is discussed in Chapter 164.

Concerns related to the development of hyponatremia in hospitalized patients have led to the recommendation that an isotonic fluid be used for *maintenance* fluids to reduce the incidence of hyponatremia.[117,118] However, excess administration of 0.9% NaCl can result in ICF dehydration and chloride overload leading to metabolic acidosis. A *balanced* electrolyte solution (eg, lactated Ringer's, Plasma-Lyte®) may be preferred for this reason.[118] Excess sodium administration also carries the risk of hypernatremia and volume overload, especially in vulnerable patients. While isotonic fluids may be appropriate for some hospitalized patients, it is important to remember that *maintenance* fluids are appropriate when used as intended (ie, in patients who are euvolemic with no excess ongoing fluid losses and normal kidney function). Careful attention to the sodium content of IV fluids administered to all hospitalized patients is warranted.

Treatment of hyperglycemia-induced osmotic diuresis consists of correcting the hyperglycemia with insulin, as well as administering 0.9% NaCl until signs of hypovolemia resolve. Once hemodynamic stability is restored, the free water deficit can be corrected as described above.

Hypernatremia in patients undergoing a post-obstructive diuresis should be treated with a hypotonic fluid (eg, 0.45% NaCl [IV], Pedialyte® [oral]) administered at a rate of approximately one-half to two-thirds of the urine output over a similar time point. Oral fluid replacement is preferred, if possible. The common practice of administering IV or oral fluids to replace urine output on a 1:1 volume basis tends to perpetuate the diuresis and generally should be avoided.[119]

Euvolemic (Isovolemic) Hypernatremia

Central Diabetes Insipidus

Patients with central DI should generally receive AVP replacement therapy with desmopressin, an AVP analog (Fig. 68-3). The intranasal formulation, 1-desamino-8-D-arginine vasopressin (DDAVP), is preferred; however, oral tablets are available and may be useful in some patients. Each insufflation of intranasal DDAVP (100 mcg/mL) delivers 10 mcg of desmopressin acetate. A rhinal tube delivery system is preferred in patients requiring doses that are lower than 10 mcg or not in 10-mcg increments. In infants with congenital DI, preparation of a DDAVP dilution may be required to provide the small dosages needed. In adults, the initial intranasal DDAVP dosage is 5 to 10 mcg administered once or twice daily, titrated to a maximum dose of 40 mcg given every 8 hours. The oral starting dosage is 0.05 mg BID titrated to a maximum of 0.4 mg every 8 hours.[115]

Patients may prefer oral tablets due to the ease of administration, but not all patients will adequately respond to the oral formulation as the bioavailability is only about 5%. A 0.1 mg tablet is equivalent to 2.5 to 5 mcg of the intranasal formulation. Sublingual tablets are also available. Re-titration of the dosage is required when transitioning between dosage forms due to the unpredictable absorption. A parenteral formulation of desmopressin (4 mcg/mL) is available for either subcutaneous or IV administration and may be administered in cases when the intranasal and oral routes are not feasible or effective, or in acute settings to initiate therapy in symptomatic patients.

The desmopressin dosage should be adjusted to achieve adequate urinary concentration to control nighttime symptoms during sleep (nocturia), a daily urine volume of approximately 1.5 to 2 L, and a safe serum sodium concentration. The mean duration of action of intranasal DDAVP is 7 to 9 hours. The serum sodium concentration should be measured at 24 hours and every 3 to 4 days during the initial dosage titration period, and then every 2 to 4 months. Desmopressin administration results in non-suppressible AVP activity and presents a risk of water intoxication with excess water intake and retention. Patients must be knowledgeable of the signs and symptoms of both hyponatremia and hypervolemia. Patients who experience water intoxication may minimize the risk of a second episode by delaying one desmopressin dose each week until polyuria and thirst develop, thus demonstrating the continued need for desmopressin therapy.[120]

When there is an inadequate response to desmopressin, additional therapies may be needed. Carbamazepine increases renal sensitivity to AVP, chlorpropamide potentiates the action of circulating AVP and decreases urine output by 50%, and indapamide increases urinary osmolality and decreases serum osmolality. These medications are associated with significant adverse medication reactions and close monitoring is required if added to the patient's therapy.[115]

Nephrogenic Diabetes Insipidus

In patients with nephrogenic DI, concomitant electrolyte disturbances, if present, should be corrected, and any medications that potentially contribute to the pathogenesis should be discontinued, if possible. The free water deficit must be replaced initially. Mild cases may be managed with sufficient water intake only. Because the ongoing urinary losses are essentially free water, patients should receive hypotonic fluids to avoid excess sodium intake which could worsen hypernatremia (Fig. 68-3). Water or milk can be given enterally or D_5W can be given intravenously at a rate that slightly exceeds the urine output with a goal to normalize the serum sodium concentration at a rate no faster than 0.5 mEq/L/hr (mmol/L/hr).[121] A key goal in treating nephrogenic DI is to induce a mild ECF deficit (1-1.5 L) with a thiazide diuretic and dietary sodium restriction (85 mEq [mmol] Na^+ or 2,000 mg NaCl per day), which can decrease urine volume by as much as 50% (Table 68-9). This ECF deficit will increase proximal tubule water reabsorption, decrease the filtrate volume delivered to the distal nephron, and decrease urine volume. In a patient with a maximally dilute urine osmolality (100 mOsm/kg [mmol/kg]), each gram of salt that is avoided will reduce the obligatory urine output by 360 mL because 1 g of table salt provides an osmolar load of approximately 36 mOsm.[121] Indomethacin, 50 mg given orally three times daily, potentiates AVP activity and can be used as adjunctive therapy in patients able to tolerate the gastrointestinal (GI) adverse medication reactions. The relative benefits of other medications for nephrogenic DI, including thiazide diuretics and nonsteroidal anti-inflammatory drugs (NSAID), are not well studied; therefore, the choice of agent is primarily based on clinician preference. It is unclear if there is a significant difference in the risk of a clinically important GFR decrease when these medications are used to produce a mild ECF volume deficit. Lithium-induced nephrogenic DI can usually be treated with increased water intake because thirst is intact. If water intake is inadequate, amiloride 2.5 mg to 10 mg daily can be used as amiloride decreases lithium entry into the principal cells by inhibiting the amiloride-sensitive epithelial sodium channel (ENaC).[115] Several other medications with antidiuretic properties have been used successfully in the management of central and nephrogenic DI (Table 68-9). They may be used as adjunctive therapy or rarely as an alternative to DDAVP.

TABLE 68-9

Medications Used in Central and Nephrogenic DI

Medication	Indication	Dose
Desmopressin acetate	Central and nephrogenic	IN: 5-20 mcg q12-24hr IV/SQ: Initial, 0.25-1 mcg q12-24hr PO: Initial: 0.05-0.2 **m g** qhs; Usual: 0.1-0.8 **m g** in 2-3 doses, max 1.2 mg daily SL: 60 mcg TID; usual, 120-720 mcg daily in 2-3 doses
Chlorpropamide	Central	125-250 mg orally daily
Carbamazepine	Central	100-300 mg orally twice daily
Hydrochlorothiazide	Central and nephrogenic	25 mg orally q12-24hr
Amiloride	Nephrogenic	5-10 mg orally daily Pediatrics: 0.2 mg/kg/day in 3 doses or 20 mg/1.73 m^2/day
Indomethacin	Central and nephrogenic	50 mg orally q8-12hr

DI, diabetes insipidus; IN, intranasal; IV, intravenous; PO, oral; SL, sublingual; SQ, subcutaneous

Hypervolemic Hypernatremia (Sodium and Water Overload)

Treatment of hypervolemic hypernatremia consists of administration of D_5W and a loop diuretic to facilitate excretion of the excess sodium while replacing free water to prevent worsening of hypernatremia (Fig. 68-3). The volume needed to correct the water deficit and hypernatremia at an appropriate rate can be estimated as described previously. Furosemide, 20 to 40 mg given orally or intravenously every 6 hours, should also be administered.

The serum sodium concentration should initially be measured at least every 2 to 4 hours, and diuresis continued until signs of ECF volume overload (eg, pulmonary congestion, edema) resolve. The serum sodium concentration can be measured every 6 to 12 hours once the serum sodium concentration is less than 148 mEq/L (mmol/L) and symptoms have resolved.[2]

EDEMA

⑪ Edema, defined as a clinically detectable increase in interstitial fluid volume, is usually due to heart, kidney, or liver failure or a combination of these conditions; although, it can develop with a rapid decrease in serum albumin concentration along with excess fluid intake such as seen in the setting of burns or trauma. In an adult, edema formation is indicative of an interstitial volume increase of at least 2.5 to 3 L.

Pathophysiology

Edema develops when excess sodium is retained either as a primary defect in renal sodium excretion or as a response to a decrease in the effective circulating volume (actually the BP resulting from that volume) despite a normal or expanded ECF volume. Under these conditions, the kidneys retain all the water and sodium ingested until the effective circulating volume is restored to near normal. An increase in dietary sodium is accompanied by an increase in water intake caused by the initial increase in serum osmolality and thirst. The resultant ECF volume increase augments kidney perfusion, resulting in a transient GFR increase, which leads to enhanced sodium filtration and excretion. These homeostatic mechanisms are crucial for maintaining sodium balance, as retention of just a few milliequivalents (millimoles) of sodium per day can eventually lead to an expanded ECF volume and edema formation. An increase in the capillary hydrostatic pressure because of ECF volume expansion or an increase in central venous pressure also can lead to edema formation. Edema may also occur when there is an alteration in Starling forces within the capillary. The Starling equation denotes the relationship between factors affecting fluid movement between the capillary and interstitium. Edema may develop rapidly in patients with an acute decompensation in myocardial contractility, which leads to an elevated pulmonary venous pressure that is transmitted back to the pulmonary capillaries, and ultimately results in acute pulmonary edema.

Patients with nephrotic syndrome may initially present with edema, primarily periorbital, labial/scrotal, and lower extremity which may progress to pulmonary edema, ascites, and anasarca. There are two theories posited to explain edema in nephrotic syndrome: the *underfill* and the *overfill* hypotheses.[122,123] The underfill hypothesis states that high-grade proteinuria leads to decreased oncotic pressure due to hypoalbuminemia (most pronounced with a serum albumin concentration less than 2 g/dL [20 g/L]). Decreased oncotic pressure then leads to excess fluid movement from the intravascular space to the interstitial space (*third spacing*) causing hypovolemia, kidney hypoperfusion, activation of the renin–angiotensin–aldosterone system, and secondary renal sodium retention. The overfill hypothesis is simply that protein loss in the urine leads to primary renal sodium retention causing intravascular volume expansion, leading to fluid overflow into the interstitial space (edema). Edema mechanisms can vary between patients and also vary at different times in an individual patient. Distinguishing the predominant mechanism in individual patients with nephrotic syndrome is often challenging but clinically important, as patients who are primarily underfilled will likely have worsening hypovolemia and an elevated serum creatinine requiring volume repletion after initially tolerating diuresis.

Patients with cirrhosis initially develop ascites because of splanchnic vasodilation resulting in an increase in the pressure in the portal circulation (portal hypertension). This combination of portal hypertension and splanchnic vasodilation increases capillary pressure and permeability and facilitates the accumulation of ascites (fluid in the abdominal cavity). Ascites can cause a decrease in effective circulating volume and activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system, leading to secondary hyperaldosteronism. Subsequent renal sodium retention leads to worsened ascites, edema, and hypervolemic hyponatremia.[124]

Clinical Presentation

Edema is usually first detected in the feet or periorbital or pretibial area in ambulatory patients and in the presacral area of bed-bound individuals. Edema is described as “pitting” when a depression created by exerting pressure for several seconds over a bony prominence, such as the tibia, does not rapidly refill. Edema severity is rated on a semi-quantitative scale of 1+ to 4+ depending on the depth of the pit: 1+ = 2 mm; 2+ = 4 mm; 3+ = 6 mm; and 4+ = 8 mm.

The extent of edema should be quantified according to the areas involved. Pretibial edema, for example, should be quantified according to how far it extends up the lower leg (eg, one-third up the lower leg). Pulmonary edema, an increase in lung interstitial and alveolar water, is often evidenced by crackles (rales) upon auscultation. Rales should be quantified according to how far the crackles extend from the dependent portion of the lung(s). For example, edema limited to the ankles and feet would indicate less severe edema than edema that extends halfway up the lower legs, and crackles limited to the base of both lungs in an upright person would indicate less severe pulmonary edema than crackles throughout both lung fields. *Anasarca* is a term used to refer to a massive amount of edema generalized throughout the body.

Treatment

General Approach

Treatment goals for hypervolemic hypernatremia are to minimize edema and to improve organ function, as well as to relieve symptoms (eg, dyspnea, abdominal distention, extremity pain). The presence of edema does not always dictate the need for diuretic therapy; however, severe pulmonary edema is life-threatening and requires immediate pharmacologic treatment. Other forms of edema may be treated less acutely, with a comprehensive approach that includes not only diuretics but also sodium and water restriction and optimal treatment of the underlying disease. Sodium intake should generally be restricted to 1,000 to 2,000 mg/day. A slow judicious approach in non-life-threatening situations will help minimize complications of diuretic therapy, including excessive diuresis, impaired perfusion, azotemia, impaired cardiac output due to decreased left ventricular end-diastolic filling pressure, and electrolyte abnormalities. Fluid should be removed cautiously in patients with cirrhosis and ascites but no peripheral edema. A goal of 500 mL/day can be safely mobilized in patients with isolated ascites; higher volumes may result in decreased ECF volume and lead to elevated BUN and possibly hepatorenal syndrome.[124]

Diuretic Therapy

Diuretics are the primary pharmacologic therapy for edema when severe or when treatment of the underlying disease and sodium and water restriction are insufficient. Diuretics are categorized according to the site in the nephron where sodium reabsorption is inhibited. Loop diuretics (furosemide, bumetanide, torsemide, ethacrynic acid) inhibit the sodium–potassium–chloride (Na^+–K^+–$2Cl^-$) carrier in the loop of Henle, while thiazide and thiazide-like diuretics (hydrochlorothiazide, chlorothiazide, chlorthalidone, indapamide, metolazone) inhibit the Na^+–Cl^- carrier in the distal tubule. Potassium-sparing diuretics inhibit the sodium channel in the cortical collecting duct either directly (triamterene, amiloride) or by interfering with aldosterone activity (spironolactone, eplerenone). Acetazolamide, a carbonic anhydrase inhibitor, acts in the proximal convoluted tubule and has been used in patients with diuretic resistance. Diuretic efficacy in patients with edema depends on the amount of filtered sodium normally reabsorbed at its site of action, the amount of sodium reabsorbed distal to its site of action, adequate medication delivery to the site of action, and the amount of sodium reaching the site of action.[29]

All diuretics act by inhibiting sodium reabsorption in the renal tubules, increasing the fractional excretion of sodium (FeNa). Loop diuretics are the most potent diuretics, as evidenced by the fact that they increase peak FeNa from normal (1% [0.01] or less) to 20% to 25% (0.20-0.25). Thiazide- and potassium-sparing diuretics are less potent and increase peak FeNa only to 3% to 5% (0.03-0.05) and 1% to 2% (0.01-0.02), respectively.[29] Although a large portion of the filtered sodium is reabsorbed in the proximal nephron, the efficacy of proximal-acting diuretics (acetazolamide) is limited by excess fluid and sodium reabsorption in the loop of Henle. Furthermore, sodium reabsorption by the distal tubule can compensate for reduced reabsorption in the loop of Henle when sodium intake is high.

The pharmacogenomics of diuretic therapy, particularly the thiazides, have been studied extensively in the setting of hypertension therapy.[125] Multiple genetic polymorphisms possibly affecting diuretic activity at the site of action have been identified, but the clinical significance of these genetic variations related to patient outcomes is still being elucidated. It is likely that a complex predictive model utilizing pharmacodynamic, pharmacokinetic, and pharmacogenomic parameters will be necessary to predict significantly different diuretic responses and outcomes due to the potential for compensatory mechanisms in other parts of the nephron. While genetic testing for gene variants is now available, it is not yet a practical option to guide diuretic treatment.

The effectiveness of thiazide and loop diuretics is dependent on the medication concentration in the tubular lumen. These diuretics are delivered to the tubular lumen via active transport by the proximal tubular cells. Osmotic diuretics are freely filtered into the tubular lumen in the proximal tubule; whereas spironolactone reaches mineralocorticoid receptors in the cortical collecting duct via diffusion from the systemic circulation.[29] A threshold concentration of loop or thiazide diuretic must be delivered to the respective site of action to achieve a natriuresis. Once the threshold concentration is achieved, a further diuretic dose increase will not elicit an increased diuretic response. Thus, a *ceiling dose* for these diuretics is recognized. In healthy subjects, administration of IV furosemide 40 mg results in excretion of 200 to 250 mEq (mmol) of sodium in 3 to 4 L of urine over a 3- to 4-hour period.[29]

Loop diuretics, except torsemide, have a rapid onset but short half-life requiring administration every 2 to 3 hours while thiazide diuretics have a longer half-life allowing for less frequent (once daily) dosing (Table 68-10). Table 68-11 lists the maximal effective doses and dosing intervals for loop diuretics in patients with cirrhosis, HF, nephrotic syndrome, and kidney insufficiency.

TABLE 68-10

Characteristics of Thiazide Diuretics

Diuretic	Duration of Action	Initial Daily Dosage	Sequential Nephron Blockade	Maximum Total Daily Dose
Chlorothiazide	6-12 hr	250-500 mg once or twice	500-1,000 mg once plus loop diuretic	1,000 mg
Chlorthalidone	24-72 hr	12.5-25 mg once		100 mg
Hydrochlorothiazide	6-12 hr	25 mg once or twice	25-100 mg once or twice plus loop diuretic	200 mg
Indapamide	36 hr	2.5 mg once		5 mg
Metolazone	12-24 hr	2.5 mg once	2.5-10 mg plus loop diuretic	20 mg

TABLE 68-11

Characteristics of Loop Diuretics

Diuretic	Dosing Interval	Recommended Doses				GFR 10-50 mL/min (0.17-0.83 mL/s)	GFR <10 mL/min (0.17 mL/s)	Maximum Total Daily Dose[a]
		Normal	Cirrhosis	HF	Nephrotic Syndrome			
Furosemide								
IV	6-8 hr	10-40 mg	40 mg	40-80 mg	120 mg	80 mg	200 mg	200 mg or 160 mg/hr
Oral	6-8 hr	20-80 mg	80 mg	80-160 mg	240 mg	160 mg	320-400 mg	600 mg
Bumetanide								
IV/oral	6-8 hr	1 mg	1 mg	2-3 mg	3 mg	2-3 mg	8-10 mg	10 mg
Torsemide								
IV/oral	24 hr	15-20 mg	10-20 mg	20-50 mg	50 mg	20-50 mg	50-100 mg	200 mg
Ethacrynic acid[b]								
IV	8-12 hr[c]	0.5-1 mg/kg (max 100 mg)						
Oral	12-24 hr	25-100 mg	50-100 mg	50-100 mg				400 mg

HF, heart failure; GFR, glomerular filtration rate.

[a] Although these doses are generally accepted maximal doses, higher doses may be required due to insufficient quantities in the renal tubular fluid.

[b] Rarely used because of higher rates of ototoxicity and relative insolubility; may be used in a patient with a sulfa allergy.

[c] Repeat doses not routinely recommended.

Patients with kidney insufficiency often require larger diuretic doses to achieve adequate medication concentrations at the site of action. The natriuretic response is decreased in patients with kidney insufficiency because the filtered sodium load falls proportionately as GFR declines. This effect can be partially overcome by administering diuretics more frequently or by using a continuous infusion, a method commonly employed in critically ill patients. Continuous delivery will limit the effect of the post-diuresis sodium retention in the distal nephron. Table 68-12 lists initial continuous infusion rates based on creatinine clearance and maximum recommended infusion rates.

TABLE 68-12

Continuous Infusion Rates for Loop Diuretics

Medication	Initial Infusion Rate Based on Creatinine Clearance (CrCl)			Maximum Infusion Rate	
	CrCl < 25 mL/min (0.42 mL/s)	CrCl 25-75 mL/min (0.42-1.25 mL/s)	CrCL > 75 mL/min (1.25 mL/s)	Undiluted bolus	Continuous infusion
Bumetanide	1-2 mg/hr	0.5-1 mg/hr	0.5 mg/hr	5 mg/min	0.17 mg/min[a] (up to 5 mg)
Furosemide	20-40 mg/hr	10-20 mg/hr	10 mg/hr	40 mg/min	4 mg/min
Torsemide	10-20 mg/hr	5-10 mg/hr	5 mg/hr	100 mg/min	3.1 mg/hr[b]

[a] Doses of 2-5 mg may be given over 30-60 minutes in a suitable infusion fluid.

[b] Studies used a 100-mg total daily dose as a 25-mg injection over 2 minutes (25% of total daily dose) followed by an infusion of 3.1 mg/hr over 24 hours (75% of total daily dose).

Loop diuretic resistance can be caused by pronounced sodium reabsorption in the distal nephron when sodium absorption in the loop of Henle is blocked. If sodium intake is not restricted, this distal sodium reabsorption can compensate entirely for loop diuretic-induced sodium loss. Patients with diuretic-resistant edema can be treated with a loop diuretic and metolazone. Metolazone should be given first and allowed sufficient time to start blocking distal sodium reabsorption to maximize loop diuretic efficacy.

Impaired diuretic delivery to the site of action is another mechanism of diuretic resistance. Patients with HF and a normal GFR may have impaired oral furosemide absorption. An adequate diuresis is most readily sustained by increasing the frequency of diuretic administration, but a higher dose may also be effective (Fig. 68-4). Absorption of orally administered loop diuretics can be compromised by GI edema and delayed gastric emptying, conditions often seen in critically ill patients.

Inadequate medication concentration at the site of action also can be caused by decreased perfusion as might be seen in patients with decompensated HF or those with decreased kidney perfusion. Due to extensive albumin binding (more than 95%), little of these agents reach the tubule lumen by filtration, and they are almost exclusively transported into the proximal tubule lumen by active secretion via the organic acid secretory pathway.[29] When albumin binding is inhibited by concurrent sulfasoxazole administration, diuretic resistance persists, suggesting a decrease in intrinsic tubular sensitivity to loop diuretics.[126] This impaired natriuretic response can be overcome by using higher diuretic doses to increase unbound medication delivery to the secretory site in the nephron. Decreased intrinsic diuretic activity with repeated dosing may also play a role in diuretic resistance; the mechanism of which is not well understood. A combination of a loop diuretic with a distally acting diuretic is generally necessary to promote a natriuresis that exceeds distal tubular sodium reabsorption in patients with nephrotic syndrome (Fig. 68-5).[127]

In patients with cirrhosis, secondary hyperaldosteronism from activation of the renin–angiotensin–aldosterone system plays a major role in the pathogenesis of edema. Therefore, these patients should initially be treated with an aldosterone antagonist (eg, spironolactone) in the absence of impaired GFR and hyperkalemia (Fig. 68-6). Thiazides can then be added for patients with a creatinine clearance greater than 50 mL/min (0.83 mL/s). For those with diuretic-resistant edema, a loop diuretic may be used instead of the thiazide. Patients with impaired GFR (creatinine clearance less than

40 mL/min [0.67 mL/s]) will require a loop diuretic, with addition of a thiazide in those who do not achieve adequate diuresis.[128]

Adverse medication reactions associated with loop and thiazide diuretics include hypokalemia, excess ECF volume loss (hypovolemia), hypomagnesemia, metabolic alkalosis, and hyperuricemia. Patients with refractory edema treated with high-dose synergistic combinations are at highest risk for developing hypokalemia. As noted earlier, sodium imbalance is a concern with diuretic therapy: hyponatremia with thiazides, hypernatremia with loops. Calcium imbalance also can occur with diuretic use: hypocalcemia with loops, hypercalcemia with thiazides. Thiazide-induced hypercalcemia is more common in patients with mild subclinical hyperparathyroidism. Loop diuretics cause hypercalciuria and can lead to bone disorders (osteopenia, osteoporosis), kidney stones, or nephrocalcinosis when used chronically. Chronic use of potassium-sparing diuretics can cause a mild metabolic acidosis and hyperkalemia. Patients with moderate-to-severe kidney dysfunction or those receiving NSAIDs, ACEIs, or ARBs are at highest risk for hyperkalemia. In addition, spironolactone can cause reversible gynecomastia in about 10% of men receiving it, and in about 50% of men receiving 150 mg/day or more. This adverse medication reaction has not been associated with eplerenone.[129]

Evaluation of Therapeutic Outcomes

In patients with significant edema, volume status must be monitored carefully to ensure adequate tissue perfusion. Patients should be monitored by careful history and intermittent physical examination to detect signs and symptoms of edema as well as adverse effects. Physical examination should include measurement of BP and pulse in either supine or seated positions and after standing for 2 to 3 minutes to assess for orthostasis. ECF volume can be estimated based on the height of the jugular venous pressure, extent of edema, heart and lung auscultation, and skin turgor. Follow-up monitoring 10 to 14 days after therapy initiation should include determinations of serum sodium, potassium, chloride, bicarbonate, magnesium, calcium, BUN, serum creatinine, and uric acid. A new steady-state balance will have developed over that time period and further fluctuations in ECF volume and electrolyte balance generally do not occur in the absence of a change in clinical status, diuretic dosage, or dietary intake. Repeated blood tests generally are not necessary at every visit unless there is a change in the patient's clinical status.

ABBREVIATIONS

ACEI	angiotensin-converting enzyme inhibitor
AQP2	aquaporin 2
ARB	angiotensin receptor blocker
AVP	arginine vasopressin, also known as vasopressin and antidiuretic hormone (ADH)
ATPase	adenosine triphosphatase
BP	blood pressure
BUN	blood urea nitrogen
CNS	central nervous system
D_5W	dextrose 5% in water
DDAVP	1-desamino-8-D-arginine vasopressin
DI	diabetes insipidus
ECF	extracellular fluid
FeNa	fractional excretion of sodium
GFR	glomerular filtration rate
GI	gastrointestinal
HF	heart failure
ICF	intracellular fluid
ICU	intensive care unit
IV	intravenous
NSAID	nonsteroidal anti-inflammatory drug
ODS	osmotic demyelination syndrome
SIADH	syndrome of inappropriate antidiuretic hormone secretion
SGLT2	sodium-glucose co-transporter-2
TBW	total body water
VRA	vasopressin receptor antagonist

V_d	volume of distribution

SELF-ASSESSMENT QUESTIONS

1. A 76-year-old woman (weight, 65 kg; height, 170 cm) has been hospitalized for a few days. Her laboratory results this morning reveal a serum sodium of 110 mEq/L [mmol/L]. What is this patient's sodium deficit (note: use 120 mEq/L [mmol/L] as the desired safe serum sodium concentration)?

   A. 278 mEq (mmol)

   B. 293 mEq (mmol)

   C. 732 mEq (mmol)

   D. 878 mEq (mmol)

2. Which of the following is the appropriate *initial* treatment for a patient with nephrogenic DI?

   A. Amiloride

   B. Furosemide

   C. Enteral water

   D. 0.9% NaCl

3. An adult patient was initiated on bumetanide approximately 1 week ago. During a follow-up appointment, she is noted to be confused, lethargic, and weak. Vital signs are taken and she is found to be hypotensive, tachycardic, and orthostatic. Laboratory studies are sent, and the serum sodium is reported as 159 mEq/L (mmol/L). Which of the following is the *most appropriate* initial intravenous fluid to administer to this patient?

   A. 0.9% NaCl

   B. Dextrose 5% in water

   C. 3% NaCl

   D. 0.45% NaCl

4. An adult patient with type 1 diabetes mellitus is admitted with a serum glucose concentration of 990 mg/dL (54.9 mmol/L) and a serum sodium concentration of 124 mEq/L (mmol/L). What is the *best* estimate of the patient's serum sodium concentration corrected for hyperglycemia?

   A. 109 mEq/L (mmol/L)

   B. 132 mEq/L (mmol/L)

   C. 139 mEq/L (mmol/L)

   D. 154 mEq/L (mmol/L)

5. An adult patient is admitted with a severe metabolic acidosis secondary to diarrhea. The patient is administered sodium bicarbonate to correct the acidosis. Excessive sodium bicarbonate administration could result in which of the following sodium disorders?

   A. Hypovolemic hypernatremia

   B. Euvolemic hypernatremia

   C. Hypervolemic hypernatremia

   D. Hypervolemic hyponatremia

6. What are the usual determinants of serum osmolality?

   A. Serum sodium, glucose, and blood urea nitrogen concentrations

   B. Serum sodium, potassium, and glucose concentrations

   C. Serum potassium, bicarbonate, and glucose concentrations

   D. Serum sodium, bicarbonate, and blood urea nitrogen concentrations

7. A 75-year-old woman (weight, 60 kg) is hospitalized after suffering a stroke. Her serum sodium concentration has been trending downward since admission (baseline 137 mEq/L [mmol/L]; third hospital day 121 mEq/L [mmol/L]). Upon physical examination, she has good skin turgor, no lower extremity edema, and appears hydrated. The medical team is considering the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) or cerebral salt wasting syndrome among their differential diagnoses. Which of the following is *most helpful* in differentiating between these two diagnoses?

   A. Serum sodium concentration

   B. Serum osmolality

   C. Serum antidiuretic hormone concentration

   D. Urine sodium concentration

8. The medical intern asks your assistance in developing a treatment plan for a patient with severe hyponatremia who is seizing. The serum sodium concentration is 110 mEq/L (mmol/L), which is felt to be an acute change from baseline based on laboratory values from the previous day. An order is placed for an initial dose of 3% NaCl. Which sodium concentration below represents the maximum sodium increase recommended in the *first one hour* of treatment in this setting?

   A. 111 mEq/L (mmol/L)

   B. 113 mEq/L (mmol/L)

   C. 115 mEq/L (mmol/L)

   D. 120 mEq/L (mmol/L)

9. A 48-year-old woman with a history of heart failure with reduced ejection fraction (left ventricular ejection fraction 25% [0.25]) presents to clinic for routine follow-up. She has increased lower extremity edema and has experienced an 8-lb (3.6 kg) weight gain over the previous 2 weeks. She reports no dietary indiscretions and is adherent to her guideline-directed medical therapy. Her serum creatinine is at baseline (1.1 mg/dL [97 µmol/L]). She is taking furosemide 120 mg orally three times daily at home. Which of the following is the *most appropriate* outpatient intervention?

   A. Continue the current furosemide dose

   B. Increase furosemide to 240 mg orally three times daily for the next 2 days

   C. Initiate metolazone 5 mg orally before the first furosemide dose each morning

   D. Initiate furosemide 40 mg IV every 4 hours

10. A 24-year-old construction worker (weight, 70 kg; no significant past medical history) experiences a syncopal episode on the roof of a new apartment building on a hot summer day (100°F [37.8°C]). He presents to the emergency department with a BP of 76/30 mm Hg, HR of 138 bpm, and significant orthostasis. His serum sodium is 164 mEq/L (mmol/L). Which of the following is the *most appropriate* initial intervention?

    A. A 500-mL IV bolus of Dextrose 5% in water (D_5W) over 30 minutes

    B. A 750-mL bolus of oral rehydration solution ingested over 4 hours

    C. A 1,000-mL IV bolus of 0.9% NaCl over 30 minutes

    D. A 1,000-mL IV bolus of Dextrose 5%/0.45% NaCl over 30 minutes

11. Spironolactone reaches its site of action in the cortical collecting duct via which of the following processes?

    A. Diffusion from the systemic circulation

    B. Active secretion by proximal tubular cells

    C. Glomerular filtration by proximal tubular cells

    D. Reabsorption by proximal tubular cells

12. Which of the following is the most appropriate *maintenance* fluid for adults to avoid the occurrence of iatrogenic hypernatremia?

    A. Dextrose 5%/0.45% NaCl with 20 mEq (mmol) KCl/L

    B. Dextrose 5%/0.2% NaCl with 20 mEq (mmol) KCl/L

    C. Dextrose 5%/0.9% NaCl with 20 mEq (mmol) KCl/L

    D. Lactated Ringer's solution

13. A 26-year-old (NKDA) who takes lithium 1,200 mg daily presents to clinic with a serum sodium concentration of 145 mEq/L (mmol/L) and complaints of excessive urination over the previous few days. The patient's psychiatrist recommends continuing the lithium due to the patient's treatment-resistant bipolar disorder. Which of the following is the most appropriate recommendation for this patient?

    A. Indomethacin 50 mg by mouth twice daily

    B. Amiloride 5 mg by mouth daily

    C. Sodium restriction to 4,000 mg NaCl per day

    D. Demeclocycline 300 mg by mouth three times daily

14. How will the administration of 1,800-mL of D5/0.45% NaCl change the extracellular fluid (ECF) and intracellular fluid (ICF) compartment volumes?

    A. Increase the ECF by 1,800 mL

    B. Increase the ECF and ICF by 900 mL each

    C. Increase the ECF by 1,200 mL and the ICF by 600 mL

    D. Increase the ECF by 1,500 mL and the ICF by 300 mL

15. A 32-year-old pregnant woman is admitted to the hospital with nausea and disorientation. She is diagnosed with syndrome of inappropriate secretion of antidiuretic hormone (SIADH). The patient's serum sodium has decreased from 130 mEq/L (mmol/L) to 118 mEq/L (mmol/L), and she is becoming increasingly confused and somnolent. The patient has a history of anaphylaxis when receiving a sulfa-containing medication. Which of the following is the *most appropriate* treatment to initiate in this patient?

    A. Demeclocycline 300 mg by mouth three times daily

    B. Dietary sodium restriction to 2,000 mg/day

    C. Furosemide 40 mg by mouth twice daily

    D. Tolvaptan 15 mg by mouth daily

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Sodium deficit is calculated using the following equation: Na deficit (mEq or mmol) = [(Na_D – Na_S) × TBW], where Na_D is the goal or desired serum sodium; Na_S is the patient's current serum sodium concentration; and, TBW is the patient's currently estimated total body water. For a woman older than 70 years, TBW is estimated to be 0.45 L/kg × actual weight (kg) so the Na deficit = (120 – 110) × (65 × 0.45) = 293 mEq (mmol).

2. **C.** Patients with nephrogenic DI produce large amounts of hypotonic urine (essentially free water) due to a decreased kidney response to AVP. Patients should receive hypotonic fluids to avoid excess NaCl intake and worsening hypernatremia. Enteral water or milk is preferred, but intravenous D5W or other hypotonic fluid can be given if necessary depending on the severity of the hypernatremia and water loss. Thiazide diuretics or indomethacin may be given as adjunctive therapy to dietary sodium restriction and hypotonic fluids; however, loop diuretics are not recommended.

3. **A.** Patients with hypovolemic hyponatremia should be treated initially with an isotonic fluid (ie, 0.9% NaCl, lactated Ringer's) which will remain in the ECF until they are hemodynamically stable. Once the intravascular volume is restored, hypotonic fluids (ie, 0.45% NaCl, D_5W) may be administered to restore the ICF volume.

4. **C.** Hyperglycemia can cause hypertonic hypovolemic hyponatremia by increasing the effective osmoles in the ECF. Based on the volume of distribution of glucose, a 1.5 to 1.9 mEq/L (mmol/L; mean, 1.7 mEq/L [mmol/L]) increase in the serum sodium concentration for every 100 mg/dL

(5.6 mmol/L) decrease in the serum glucose concentration to 100 mg/dL (5.6 mmol/L) can be predicted. Thus, the predicted serum sodium concentration would be: (990-100/100 × 1.7) + 124 = 139 mEq/L (mmol/L). Or for results expressed in SI units ((54.9-5.6)× 0.29) + 124 = 138 mmol/L, which is remarkably similar for the two equations.

5. **C.** Hypertonic fluid administration and sodium-containing medications like sodium bicarbonate can result in hypernatremia and an expanded ECF volume. Sodium bicarbonate provides 1 mEq sodium for each 1 mEq bicarbonate infused. The sodium load can be excessive if treating a severe metabolic acidosis. Even slightly hypertonic, sodium-containing solutions (ie, 0.9% NaCl, lactated Ringer's) can lead to sodium accumulation, particularly if a dilute urine is excreted.

6. **A.** The primary determinant of serum osmolality is the sodium concentration; however, glucose and blood urea nitrogen also contribute to serum osmolality and are included in the equation for estimating serum osmolality. Serum osmolality can be estimated as: $Osm_S = (2 \times Na_S) + (glucose_S/18) + (BUN/2.8)$, where Osm_S is the serum osmolality in mOsm/kg; Na_S is the serum sodium concentration in mEq/L; $glucose_S$ is the serum glucose concentration in mg/dL; and BUN is the blood urea nitrogen concentration in mg/dL. Serum osmolality can also be estimated as: $Osm_S = (2 \times Na_S) + (glucose_S) + (BUN)$, where Osm_S is the serum osmolality in mmol/kg; Na_S is the serum sodium concentration in mmol/L; $glucose_S$ is the serum glucose concentration in mmol/L; and BUN is the blood urea nitrogen concentration in mmol/L.

7. **D.** The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and cerebral salt wasting (CSW) syndrome can both occur in patients with intracranial disorders. Both SIADH and CSW result in hypotonic hyponatremia with a low serum osmolality and high urine osmolality and cannot be differentiated by the serum sodium concentration. CSW will result in a significantly high urine output and high urine sodium concentration (>20 mEq/L [mmol/L]); however, patients with SIADH will have a lower urine output and a variable urine sodium concentration depending on the severity. Additionally, patients with SIADH will be euvolemic, whereas those with CSW will be hypovolemic; thus, appropriate volume assessment is important. Serum ADH levels can be primarily high with SIADH or rise secondary to volume depletion with CSW.

8. **C.** In patients with acute severe symptoms (eg, seizures) related to hyponatremia, the serum sodium concentration should be increased with 3% NaCl by no more than 5 mEq/L (mmol/L) in the first hour of treatment. The goal should be to increase the serum sodium concentration by no more than 8 to 12 mEq/L (mmol/L) during the first 24 hours but treatment will need to be continued until acute, life-threatening symptoms resolve.

9. **C.** The patient needs more aggressive diuresis due to her lower extremity edema and significant 2-week weight gain. The patient likely is experiencing diuretic resistance due to chronic dosing; therefore, adding a thiazide-like diuretic like metolazone for sequential nephron blockade is appropriate. While it is possible to increase the furosemide oral dose, 600 mg is the maximum recommended total daily dose. The frequency of furosemide administration could also be increased, but this change would likely lead to adherence issues. Continuing the current regimen would be inappropriate now. Intravenous furosemide is not a reasonable option for outpatient therapy, and there were no symptoms presented worrisome enough to warrant hospitalization now.

10. **C.** In patients with hypovolemic hypernatremia who are severely dehydrated, volume resuscitation with IV lactated Ringer's or 0.9% NaCl at a rate of 1,000 mL or 20 mL/kg given over 30 minutes can be given until the patient is hemodynamically stable and mental status improves. Oral therapy is inappropriate in a hemodynamically unstable patient. Once intravascular volume is restored, 0.45% NaCl, D_5W, or another hypotonic fluid can be infused to correct the water deficit.

11. **A.** Spironolactone gains access to mineralocorticoid receptors in the cortical collecting duct through diffusion from the systemic circulation. Osmotic diuretics are freely filtered into the tubular lumen in the proximal tubule; whereas, thiazide and loop diuretics are delivered to the tubular lumen via active transport by the proximal tubular cells.

12. **A.** Recurrent iatrogenic hypernatremia can be prevented by avoiding infusing too much hypertonic solution, providing adequate amounts of *maintenance* fluids, and replacing ongoing abnormal losses. The standard maintenance fluid for adults is Dextrose 5%/0.45% NaCl with 20 mEq (mmol) KCl/L. Isotonic maintenance fluids may be appropriate for some patients but increase the risk of hypernatremia, volume overload, and metabolic acidosis (due to the chloride load).

13. **B.** Lithium should be discontinued, if possible, in patients with lithium-induced nephrogenic diabetes insipidus. When discontinuation is not possible, the concomitant use of the potassium-sparing diuretic amiloride is recommended. Serum lithium concentrations should be carefully monitored in patients taking amiloride because diuretic-induced volume depletion may increase lithium reabsorption and cause supratherapeutic

levels.

14. **C.** A 0.45% NaCl solution will distribute as follows: 67% within the extracellular fluid (ECF) and 33% within the intracellular fluid (ICF). The fact that it is called “half normal saline” can be misleading if you think that half goes into the ICF and half stays in the ECF. The sodium in 0.45% NaCl (half of that in 0.9% NaCl, 77 mEq/L [mmol/L]) will stay in the ECF compartment keeping 50% of the water with it (900 mL). The remaining 900 mL has no sodium to keep it in the ECF, so it will distribute 33% into the ECF (300 mL) and 67% into the ICF (600 mL). The resulting distribution is 1,200 mL in the ECF and 600 mL within the ICF. Dextrose does not affect the fluid distribution because in low concentrations it freely passes through the cell membranes and is not an effective osmole.

15. **D.** Usual treatment for SIADH includes water restriction with demeclocycline, loop diuretics, and vasopressin receptor antagonists (VRAs) being added in patients whose sodium concentration does not respond adequately to water restriction or in whom adherence with water restriction is challenging. Demeclocycline should not be used during pregnancy or in children younger than 8 years. Furosemide should not be given to this patient due to her history of anaphylaxis with a sulfa-containing medication. In addition to water restriction, a VRA would be an appropriate choice for this patient.

Chapter 69: Disorders of Calcium and Phosphorus Homeostasis

Angela L. Bingham

KEY CONCEPTS

KEY CONCEPTS

1. Severe acute hypercalcemia can result in cardiac arrhythmias, whereas chronic hypercalcemia can lead to calcium deposition in soft tissues including blood vessels and the kidney.

2. The correction of hypercalcemia can include multiple pharmacotherapeutic modalities such as hydration, diuretics, bisphosphonates, and corticosteroids, depending on the etiology and acuity of the hypercalcemia.

3. Hypocalcemia is typically associated with an insidious onset; however, some medications such as cinacalcet are associated with rapid decreases in serum calcium.

4. Acute treatment of hypocalcemia requires calcium supplementation whereas chronic management may require other therapies such as vitamin D to maintain serum calcium concentrations.

5. Hyperphosphatemia occurs most frequently in patients with chronic kidney disease (CKD).

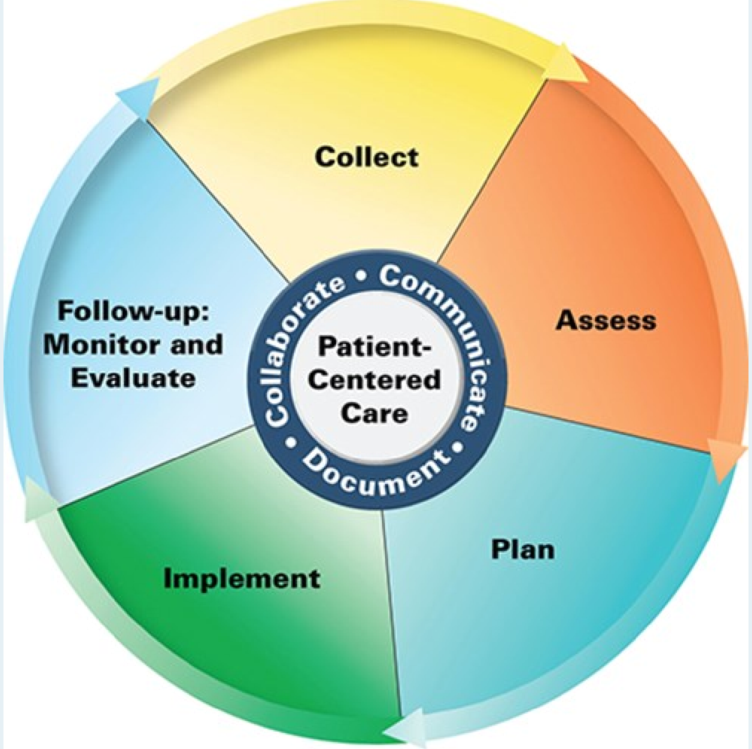
6. Treatment of nonemergent hyperphosphatemia includes the use of phosphate binders to decrease absorption of phosphorus from the gastrointestinal (GI) tract.

7. Hypophosphatemia is a relatively common complication among critically ill patients.

8. Treatment of acute hypophosphatemia usually requires intravenous (IV) phosphorus supplementation.

PATIENT CARE PROCESS

Patient Care Process for the Management of Hypercalcemia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex)
- Patient history (past medical, family, social—dietary habits)
- Evaluate symptoms (see the "Clinical Presentation: Hypercalcemia" section)
- Current medications, including over-the-counter medications, herbal products, nutritional supplements
- Objective data (see the "Clinical Presentation: Hypercalcemia" section)
    - Blood pressure, heart rate, height, weight
    - Labs (serum calcium and albumin, ionized calcium when available)
    - Other diagnostic tests when indicated (eg, ECG)

Assess

- Plausible etiology for hypercalcemia (see Table 69-1)
- Acuity of symptoms and urgency for treatment (see Fig. 69-2)
- Current medications and dietary intake that may contribute to or worsen hypercalcemia
- Kidney function (eg, serum creatinine, creatinine clearance)
- Serum calcium goal

Plan*

- Pharmacotherapy based on etiology of hypercalcemia including specific dose, route of administration, frequency of administration, and anticipated duration of treatment (see Table 69-2)

- Monitoring parameters include efficacy (eg, reduction in serum calcium, resolution of symptoms), safety (adverse medication reactions), and timeframe (see Table 69-2)
- Patient education (eg, purpose of treatment, medication therapy, expected time to reduce calcium, need for future medications)

Implement*

- Provide patient education regarding all elements of treatment plan
- Schedule follow-up based on acuity and symptoms

Follow-up: Monitor and Evaluate

- Measure serum calcium to determine response
- Presence of adverse medication reactions
- Consider alternative medication management if desired reduction in calcium is not achieved

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Skeletal Endocrine Control” in Khan Academy by Tracy Kim Kovach. This ~8-minute video provides a brief overview of calcium and phosphorus homeostasis. The video is useful to enhance students understanding regarding the COLLECT and ASSESS steps in the patient care process: <https://www.khanacademy.org/test-prep/mcat/organ-systems/the-skeletal-system/v/skeletal-endocrine-control>.

INTRODUCTION

Disorders of calcium and phosphorus are common complications of multiple acute and chronic diseases. These disorders are frequently seen in the acute care setting; however, they are also often present in ambulatory patients, usually in a less severe state. The consequences of electrolyte disorders can range from asymptomatic to life-threatening, requiring hospitalization and emergent treatment. The maintenance of fluid and electrolyte homeostasis requires adequate functioning and modulation by multiple hormones on tissues of multiple organ systems.

Many common medication therapies can disturb the normal homeostatic mechanisms that maintain calcium and phosphorus balance. In addition, with some medication therapies, toxicity is enhanced when underlying electrolyte disorders are present. Medication-induced disorders typically respond well to discontinuation of the offending agent(s); however, additional therapies are sometimes required to correct the disorder. This chapter reviews the etiology, classification, clinical presentation, and therapy for the most common disorders of calcium and phosphorus homeostasis.

DISORDERS OF CALCIUM HOMEOSTASIS

The maintenance of physiologic calcium concentrations in the intracellular and extracellular spaces is vital for the preservation and function of cell membranes, propagation of neuromuscular activity, regulation of endocrine and exocrine secretory functions, blood coagulation cascade, platelet adhesion process, bone metabolism, muscle cell excitation/contraction coupling, and mediation of the electrophysiologic slow-channel response in cardiac and smooth-muscle tissues.

The disorders of calcium homeostasis are related to the calcium content of the extracellular fluid (ECF), which is tightly regulated and comprises less than 0.5% of the total body stores of calcium. Skeletal bone contains more than 99% of total body stores of calcium.[1] ECF calcium is moderately bound to plasma proteins (40%-50%), primarily albumin.[1] Ionized or free calcium is the biologically active form and is the fraction that is homeostatically regulated.[1] Extracellular calcium, however, is most commonly measured as the total serum calcium concentration, which includes both bound and unbound calcium. The normal total calcium serum concentration range is 8.6 to 10.2 mg/dL (2.15-2.55 mmol/L).[1]

Proper assessment of total serum calcium concentration includes measurement of the patient's serum albumin concentration. Hypoalbuminemia, which can be associated with many chronic disease states, is probably the most common cause of "laboratory hypocalcemia." Patients remain asymptomatic because the unbound or ionized fraction of serum calcium remains normal (normal range, 4.48-5.2 mg/dL [1.12-1.30 mmol/L]).[1] A corrected total serum calcium concentration can be calculated based on the measured total serum calcium and the difference between a patient's measured albumin concentration and the normative value of 4 g/dL (40 g/L) by the following equations:

[redacted]Math input error

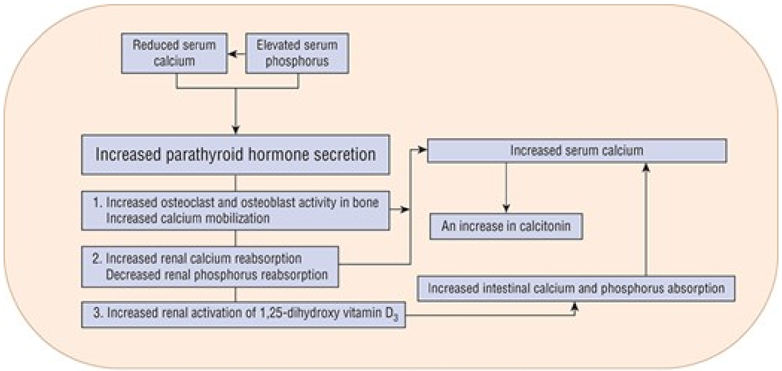
or

[redacted]Math input error

The concentration of ionized calcium is closely regulated by the interactions of parathyroid hormone (PTH), phosphorus, vitamin D, and calcitonin (Fig. 69-1). PTH increases serum calcium concentrations by stimulating calcium release from bone, increasing renal tubular reabsorption, and enhancing absorption in the GI tract secondary to increased kidney production of 1,25-dihydroxyvitamin D_3. Vitamin D directly increases serum calcium, as well as phosphorus concentrations, by increasing GI absorption. Indirectly, it can also lead to calcium release from bone and reduced renal excretion. Calcitonin inhibits osteoclastic bone resorption. Calcitonin plasma concentrations are increased when ionized calcium concentrations are high as the body attempts to return the serum calcium concentration to the normal range. Disruption of these homeostatic mechanisms results in the clinical manifestations of hypercalcemia or hypocalcemia.

FIGURE 69-1

Homeostatic mechanisms to maintain serum calcium concentrations.



Reduced serum calcium
Elevated serum phosphorus
Increased parathyroid hormone secretion
1. Increased osteoclast and osteoblast activity in bone Increased calcium mobilization
2. Increased renal calcium reabsorption Decreased renal phosphorus reabsorption
3. Increased renal activation of 1,25-dihydroxy vitamin D3
Increased serum calcium
An increase in calcitonin
Increased intestinal calcium and phosphorus absorption

Total serum calcium and ionized calcium are poorly correlated in patients with hypoalbuminemia, critical illness, and acid-base disorders.[1] Alteration of the concentration of albumin or its binding of calcium can be expected to change the unbound fraction of total serum calcium. Each 1 g/dL (10 g/L) drop in the serum albumin concentration below 4 g/dL (40 g/L) will result in a decrease of total serum calcium concentration by 0.8 mg/dL (0.20 mmol/L).[1] This approach to calculating an albumin-adjusted calcium concentration has been found to overestimate the degree of hypercalcemia and usually fails to identify hypocalcemia in critically ill patients, because the ionized calcium concentration may be normal despite a low total serum calcium concentration in the setting of hypoalbuminemia. Therefore, ionized calcium values should be used to assess calcium status in critically ill patients.[1] Change in ECF pH is the most significant cause of changes in calcium binding to albumin. In the presence of acute metabolic alkalosis the fraction of calcium bound to albumin is increased, thus reducing the plasma concentration of ionized calcium. This can result in symptomatic hypocalcemia with manifestations such as tetany, paresthesia, muscle cramping, heart block, and seizures.[1] Conversely, metabolic acidosis decreases calcium binding to albumin and results in increased ionized calcium.

HYPERCALCEMIA

There are numerous causes of hypercalcemia (total serum calcium more than 10.2 mg/dL [2.55 mmol/L]) (Table 69-1). The most common causes of hypercalcemia are primary hyperparathyroidism and cancer.

TABLE 69-1

Etiologies of Hypercalcemia

Neoplasms

- Bone metastasis
    - Breast
    - Multiple myeloma
    - Lymphoma
    - Leukemia
- Humoral induced
    - Ovary
    - Kidney
    - Pheochromocytoma
    - Multiple endocrine neoplasia
    - Lung
    - Head and neck
    - Esophagus
    - Cervix
    - Lymphoproliferative disease

Hyperparathyroidism

- Primary
- Tertiary

Miscellaneous

- Immobilization
- Paget's disease
- Familial hypocalciuric hypercalcemia
- Adolescence
- Rhabdomyolysis

Medications

- Thiazides
- Lithium
- Vitamin D
- Vitamin A
- Calcium
- Aluminum/magnesium antacids
- Theophylline
- Tamoxifen
- Ganciclovir

Granulomatous disease

- Sarcoidosis
- Tuberculosis
- Cryptococcus
- Berylliosis
- Histoplasmosis
- Coccidioidomycosis
- Leprosy

Endocrine disease

- Adrenal insufficiency
- Hyperthyroidism
- Acromegaly

Epidemiology and Etiology

Primary hyperparathyroidism occurs predominantly after the age of 50 years and affects women 3 to 4 times more than men.[2] Hypercalcemia associated with malignancy occurs in approximately 10% to 30% of patients with cancer at some time during the course of their disease and is dependent on tumor type.[3] Cancer-associated hypercalcemia is predominantly encountered in hospitalized patients, whereas primary hyperparathyroidism accounts for the vast majority of cases in the outpatient setting.[3,4]

Pathophysiology

Hypercalcemia is the result of one or a combination of three primary mechanisms: increased bone resorption, increased GI absorption, or increased tubular reabsorption by the kidneys (see Fig. 69-1).

Many tumors secrete PTH-related protein (PTHrP), which binds to the PTH receptors in bone and kidney tissue, leading to increased bone resorption and tubular reabsorption.[5] Tumors can also secrete substances such as vitamin D, transforming growth factor, interleukins, prostaglandins, interferon, tumor necrosis factor, and granulocyte-macrophage colony-stimulating factor, which are associated with the development of hypercalcemia.[3] Hypercalcemia of malignancy is generally associated with bone metastases and is a common complication of squamous cell carcinomas of the lung, head, and neck, hematologic malignancies such as multiple myeloma and T-cell lymphomas, and carcinomas of ovary, kidney, bladder, and breast. The most frequent types of malignancy associated with hypercalcemia are multiple myeloma, breast, renal, and squamous carcinomas.[3] Breast and squamous cell lung carcinomas secrete PTHrP which binds to the type I PTH receptor (PTHR1) and enhances bone resorption.[5] In contrast, patients with multiple myeloma often develop hypercalcemia principally as the result of osteoclast-mediated bone destruction.[3]

Primary hyperparathyroidism is the most common cause of chronic hypercalcemia in the general population. Benign parathyroid adenomas account for 80% to 85% of these cases of hyperparathyroidism, parathyroid hyperplasia accounts for 15%, and parathyroid carcinoma is the cause in less than 1% of cases.[4]

Other causes of chronic hypercalcemia include medications, endocrine and granulomatous disorders, physical immobilization, high bone-turnover states (eg, adolescence and Paget's disease), and rhabdomyolysis. Increased GI absorption can be the result of excessive ingestion of vitamin D analogs, calcium supplements, and lithium. Lithium and vitamin A therapy can increase bone resorption, whereas increased renal tubular reabsorption of calcium can occur with thiazide and lithium therapy. The exact mechanism of lithium-induced hypercalcemia is unknown but may include competitive inhibition of calcium influx into cells, increasing the threshold sensitivity of the calcium-sensing receptor (CaSr) and subsequent inhibition of PTH gene transcription.[6] Addison's disease, acromegaly, and thyrotoxicosis are endocrine disorders that can lead to hypercalcemia because of increased renal tubular reabsorption and increased bone resorption. Milk-alkali syndrome is the term applied to those situations where an individual develops hypercalcemia following the ingestion of calcium and absorbable alkali (eg, calcium carbonate) and is a frequent cause of hypercalcemia in patients who are not undergoing hemodialysis.[7,8] Finally, the granulomatous disorders (eg, sarcoidosis, tuberculosis, histoplasmosis, leprosy) are associated with hypercalcemia secondary to an increase in GI and renal tubular absorption as the result of granuloma production of 1,25-dihydroxyvitamin D_2.[9]

Clinical Presentation: Hypercalcemia

CLINICAL PRESENTATION: Hypercalcemia

General

- The signs and symptoms of hypercalcemia depend on the severity and rapidity of onset.

Symptoms

- Symptoms include fatigue, weakness, anorexia, depression, anxiety, cognitive dysfunction, vague abdominal pain, and constipation. Renal symptoms can include polyuria, polydipsia, and nocturia. Rarely, severe hypercalcemia leads to acute pancreatitis.

Signs

- Kidney: Nephrolithiasis; renal tubular dysfunction, particularly decreased concentrating ability; and acute and chronic kidney disease
- Cardiovascular: Hypercalcemia also directly shortens the myocardial action potential, which is reflected in a shortened QT interval and coving of the ST-T wave. Spontaneous ventricular tachyarrhythmias and elevations in blood pressure have also been reported. Chronic hypercalcemia can lead to cardiac calcification
- Musculoskeletal: Rheumatologic complaints related to hyperparathyroidism include gout, pseudogout, and chondrocalcinosis

Laboratory Tests

- Serum calcium concentrations of more than 10.2 mg/dL (2.55 mmol/L) are considered to represent hypercalcemia. Patients with values up to 13 mg/dL (3.25 mmol/L) are generally considered to have mild or moderate hypercalcemia, whereas those with values greater than this indicate the presence of severe hypercalcemia.

Patients with mild-to-moderate hypercalcemia, that is, total serum calcium concentrations above the upper threshold of normal but less than 13 mg/dL (3.25 mmol/L) or ionized calcium concentrations less than 6 mg/dL (1.50 mmol/L) can often be asymptomatic. This is typically the case for the vast majority of patients who have medication-induced hypercalcemia or primary hyperparathyroidism.[9,10]

① The presenting signs and symptoms of severe hypercalcemia that occur if the total serum calcium concentration is more than 13 mg/dL (3.25 mmol/L) may differ depending on the acuity of onset.[1] Hypercalcemia of malignancy usually develops quickly and is accompanied by a classic symptom complex of anorexia, nausea and vomiting, constipation, polyuria, polydipsia, and nocturia.[3] Polyuria and nocturia secondary to a urinary-concentrating defect constitute some of the most frequent renal effects of hypercalcemia.[9] Hypercalcemic crisis is characterized by an acute elevation of total serum calcium to a value more than 15 mg/dL (3.75 mmol/L), acute kidney injury (AKI), and obtundation (inability to arouse).[11] If untreated, hypercalcemic crisis can progress to oliguric AKI, coma, and life-threatening ventricular arrhythmias.[9] The primary complications associated with chronic hypercalcemia (hyperparathyroidism) include metastatic calcification, hypercalciuria, and CKD secondary to interstitial nephrocalcinosis.[9]

Calcium and/or calcium–phosphorus complex deposition in blood vessels and multiple organs is a complication of chronic hypercalcemia and/or concomitant hyperphosphatemia and hyperparathyroidism. Calcium deposits in atherosclerotic lesions contribute to cardiac disease.[12] Intracardiac and arterial calcifications have been found in patients with Paget disease who have normal kidney function. It is hypothesized that similar calcification processes occur in both bone and vascular tissue, leading to cardiovascular diseases including heart failure, systolic hypertension, and ischemic heart disease.[13]

The electrocardiographic changes associated with hypercalcemia include shortening of the QT interval and coving of the ST-T wave.[9] Very high serum calcium concentrations can cause T-wave widening, indicating a repolarization defect that may be associated with spontaneous ventricular tachyarrhythmias.[9] Hypertension and arrhythmias have occurred in the setting of hypercalcemia. The effects of digoxin on cardiac conduction including lowering of the excitation threshold, shortening of the effective refractory period, and increased atrioventricular refractoriness can be potentiated by hypercalcemia.[14]

Nephrolithiasis

Nephrolithiasis (ie, kidney stones) and nephrocalcinosis (ie, calcium deposits in the kidney) are the primary renal complications arising from long-standing hypercalcemia, as the result of primary hyperparathyroidism. Stone formation is dependent on a favorable milieu within the kidney or urinary tract, such as oversaturation of the urine and/or reduced concentrations of endogenous inhibitors of crystal formation (eg, citrate or pyrophosphate). About 20% to 30% of patients with primary hyperparathyroidism exhibit nephrolithiasis.[15,16] Of note, in those patients with low glomerular filtration rates (GFRs), the 24-hour urinary calcium will actually diminish secondary to decreased production of 1,25-dihydroxyvitamin D_2. However, the fractional excretion of calcium might increase.[16] Sarcoidosis is the other hypercalcemic condition frequently associated with calcium stones.[9] Other causes of nephrolithiasis with calcium-containing stones include hypocitraturia, renal tubular acidosis, hyperoxaluria, and hyperuricosuria, which are conditions that are prevalent among bariatric surgery patients.[17,18] Stone formers who have primary hyperparathyroidism are more likely to be women, older than 50 years, and have a family history of multiple endocrine disorders.[15] High dietary sodium intake can also raise urinary calcium concentrations, perhaps due to a reduction in calcium reabsorption in the kidney, thus predisposing patients to calcium stones. Although CKD can be the ultimate result of persistent stones, it is the primary cause of kidney disease in less than 2% of the end-stage kidney disease population.

Treatment

Desired Outcome

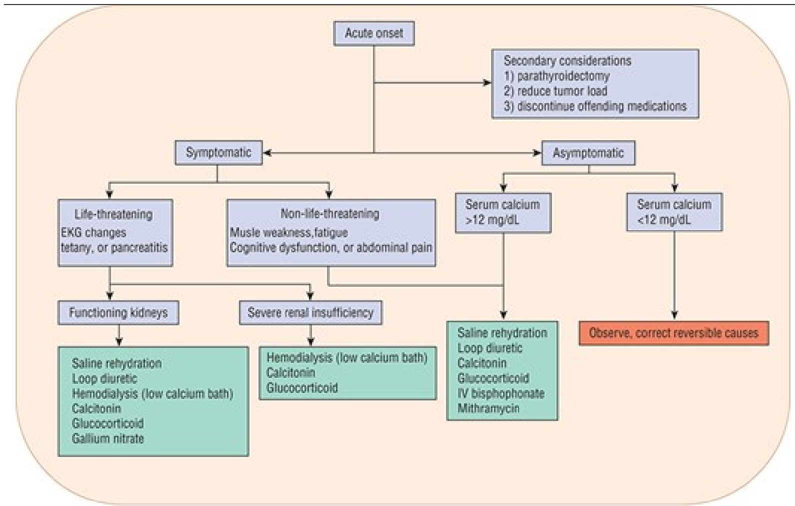
The indications for the treatment of acute hypercalcemia are dependent on the severity of hypercalcemia, acuity of its development, and the presence or absence of symptoms requiring emergent treatment (eg, necrotizing pancreatitis). The therapeutic intervention plan should be crafted to reverse signs and symptoms, restore normocalcemia within hours to days depending on acuity, and correct or manage the underlying cause of hypercalcemia.

General Approach

Chronic hypercalcemia is usually caused by an underlying medical condition or prescribed pharmacotherapies that can be resolved by successful treatment of the condition or withdrawal of the offending agent resulting in a decrease in serum calcium within days or weeks. Acute hypercalcemic episodes induced by malignancies may be mitigated by chemotherapy and/or radiation treatment. Effective surgical or medication treatment of primary hyperparathyroidism should reduce serum calcium concentrations as well as reduce the development of long-term complications such as vascular complications, CKD, and kidney stones. For treatment of nephrolithiasis, the goal in management of serum calcium is prevention of stone formation and diameter. The reduction of serum calcium should be targeted at the underlying disease state causing hypercalcemia (eg, using cinacalcet for primary hyperparathyroidism). Hypercalcemic crisis and acute symptomatic severe hypercalcemia are medical emergencies and require immediate treatment (Fig. 69-2).

FIGURE 69-2

Pharmacotherapeutic options for the acutely hypercalcemic patient. Serum calcium of 12 mg/dL is equivalent to 3 mmol/L.



Acute onset
Secondary considerations
1) parathyroidectomy
2) reduce tumor load
3) discontinue offending medications
Symptomatic
Asymptomatic
Life-threatening
EKG changes
tetany, or pancreatitis
Non-life-threatening
Musle weakness,fatigue
Cognitive dysfunction, or abdominal pain
Serum calcium >12 mg/dL
Serum calcium <12 mg/dL
Functioning kidneys
Severe renal insufficiency
Saline rehydration
Loop diuretic
Hemodialysis (low calcium bath)
Calcitonin
Glucocorticoid
Gallium nitrate
Hemodialysis (low calcium bath)
Calcitonin
Glucocorticoid
Saline rehydration
Loop diuretic
Calcitonin
Glucocorticoid
IV bisphophonate
Mithramycin
Observe, correct reversible causes

These patients may require immediate-acting interventions to promptly reduce the serum calcium concentration if electrocardiogram (ECG) changes, neurologic manifestations, or pancreatitis are present. Pharmacologic therapy consisting of volume expansion and enhancement of urinary calcium excretion with loop diuretics is usually the initial management strategy. Hemodialysis against a zero- or low-calcium dialysate solution should be considered for patients with severely impaired kidney function (CKD stage 4 or 5) who cannot tolerate large fluid loads and in whom diuretics have limited efficacy.[9]

Effective treatment of moderate-to-severe hypercalcemia in the absence of life-threatening symptoms begins with attention to the underlying disorder and correction of associated fluid and electrolyte abnormalities. Patients with primary hyperparathyroidism may require surgery, particularly if they have systemic manifestations.

Patients with malignancy often require surgical or chemotherapeutic reduction of tumor load to control the exogenous supply of cytokines and hormones (eg, PTHrP) that cause hypercalcemia. In contrast, patients with medication-induced hypercalcemia generally respond to discontinuation of the offending agent.

Pharmacologic Therapy

Symptomatic Patient Management

② For those patients with normal to moderately impaired kidney function (CKD stages 3a, 3b, and 4), the cornerstone of initial first-line treatment of severe, acute hypercalcemia or hypercalcemic crisis is volume expansion with normal saline to increase natriuresis and ultimately urinary calcium excretion (Table 69-2). Patients with symptomatic hypercalcemia are often extracellular volume depleted secondary to vomiting and polyuria; thus, rehydration with saline-containing fluids is necessary to interrupt the stimulus for sodium and calcium reabsorption in the renal tubule.[19] Rehydration can be accomplished by the rapid infusion of 1 to 2 L of normal saline followed by a maintenance infusion at 250 to 300 mL/hr, until the patient is fluid resuscitated and serum calcium approaches the upper limit of the normal range.[19] The precise rate depends on concomitant conditions (primarily cardiovascular and kidney) and magnitude of hypercalcemia. The saline infusion rate can be decreased to a rate that approximates the patient's intake of oral or IV fluids. See Chapter 68 for a thorough discussion of how to calculate water deficit and monitor patient's response to saline infusion. Loop diuretics such as furosemide (40-80 mg IV every 1-4 hours) have been used to increase urinary calcium excretion.[19] Loop diuretics block calcium (and sodium) reabsorption in the thick ascending limb of the loop of Henle and augment the calciuric effect of saline alone. Rehydration prior to loop diuretic use is critical because if dehydration persists or becomes worse, the serum calcium can actually increase because of enhanced proximal tubule calcium reabsorption.[20] The primary role for loop diuretics in the setting of hypercalcemia is to minimize the development of volume overload from the administration of saline (Fig. 69-2 and Table 69-2). Furosemide should not be used first-line as there is little evidence that supports the efficacy of furosemide in treatment of hypercalcemia.[20] Potassium chloride, 10 to 20 mEq/L (10-20 mmol/L), should be considered for addition to the saline infusion after rehydration is accomplished to prevent the development of hypokalemia that is a common adverse medication reaction of aggressive diuretic therapy. Serum magnesium concentrations should also be monitored, and magnesium replacement initiated if magnesium concentrations fall below 1.8 mg/dL (0.74 mmol/L). Rehydration with saline and administration of furosemide may result in normalization total serum calcium within 24 to 48 hours; however, patients should be monitored closely for fluid overload.[19,20] Hemodialysis with low or zero calcium dialysate is a treatment option in the case of failure or when calcium concentrations are life-threatening.[20] It should be noted that preparing a patient for hemodialysis takes time to achieve vascular access, thus, this approach is best suited for patients already receiving hemodialysis chronically.

TABLE 69-2

Medication Dosing Table for Hypercalcemia

Medication/Brand Name	Starting Dosage	Time Frame to Initial Response	Monitoring and Special Population Considerations
0.9% Saline ± electrolytes	200-300 mL/hr	24-48 hr	Electrolyte abnormalities, fluid overload CI in kidney disease, heart failure
Loop diuretics • Furosemide/Lasix® • Bumetanide/Bumex® • Torsemide	40-80 mg IV q 1-4 hr of furosemide or equivalent	N/A	Electrolyte abnormalities (potassium and magnesium), CI in patients with allergy to sulfas (use ethacrynic acid)
Calcitonin/Miacalcin®	4 units/kg q 12 hr SC/IM	1-2 hr	Facial flushing, nausea/vomiting, allergic reaction, CI in patients with allergy to calcitonin
Pamidronate/Aredia®	30-90 mg IV over 2-24 hr	2 days	Fever, fatigue, skeletal pain, CI in kidney disease
Zoledronic acid/Reclast®	4 mg IV over 15 minutes	1-2 days	Fever, fatigue, skeletal pain, CI in kidney disease
Corticosteroids	40-60 mg oral prednisone equivalents daily	3-5 days	Diabetes mellitus, osteoporosis, infection, CI in patients with serious infections, hypersensitivity

CI, contraindicated; SC, subcutaneous.

Asymptomatic Patient Management

Calcitonin

In those patients in whom saline hydration therapy is contraindicated (eg, severe heart failure, moderately-to-severely impaired kidney function), short-term therapy with calcitonin is a viable alternative agent to initiate reduction of serum calcium concentrations within 24 to 48 hours. In fact, calcitonin begins to reduce serum calcium concentrations within a few hours; however, the degree and extent of serum calcium concentration reduction are often unpredictable.[1]

Subcutaneous or IV administration of salmon calcitonin, 4 to 8 international units/kg every 12 hours, has been used to manage hypercalcemia in patients with malignancy.[3] The intranasal formulation of calcitonin has been used in doses of 200 to 400 international units daily; unfortunately, this has resulted in only mild decreases in serum calcium. The lack of significant efficacy of the synthetic intranasal formulation is the result of the lower potency and shorter duration of action as compared to salmon calcitonin.

Pharmacology

Calcitonin decreases serum calcium concentrations, primarily by inhibiting bone resorption. It can also reduce renal tubular reabsorption of calcium, thus promoting calciuresis.[3] Calcitonin from salmon sources is most commonly administered subcutaneously or intramuscularly (for larger volumes), which may rapidly lower calcium concentrations initially, but the effect can be transient.[3]

Adverse Medication Reactions

The adverse medication reactions from IV administered calcitonin (facial flushing, nausea, and vomiting) limit patient acceptability. Allergic reactions, although rare, do occur; therefore, a test dose can be given prior to starting therapy. If marked erythema and/or wheal formation does not occur within 15 minutes after administration, then therapy can be initiated. Salmon calcitonin therapy is associated with tachyphylaxis caused by antibody formation to foreign proteins or molecules resembling the calcitonin polypeptide.[21] The addition of corticosteroid therapy increases effectiveness.[3]

Bisphosphonates

Bisphosphonates block bone resorption efficiently, render the hydroxyapatite crystal of bone mineral resistant to hydrolysis by phosphatases, and also inhibit osteoclast precursors from attaching to the mineralized matrix, thus blocking their transformation into mature functioning osteoclasts.[3,9] The antiresorptive properties of this class of agents can provide long-term control of serum calcium and are the first-line therapy for cancer-associated hypercalcemia.

Pharmacology

The first-line bisphosphonates to treat hypercalcemia are pamidronate and zoledronic acid.[22] The usual dose of pamidronate is 30 to 90 mg as an IV infusion given over no less than 2 hours and up to 24 hours.[22] Pamidronate also has the advantage of single-day therapy.[22] Zoledronic acid is a high-potency bisphosphonate with demonstrated effectiveness in the treatment of hypercalcemia of malignancy. Complete response has been reported in 88.4% to 86.7% of zoledronic acid-treated versus 69.7% of pamidronate-treated patients.[23] Zoledronic acid IV doses of 4 to 8 mg given over 15 minutes have resulted in normalization of serum calcium concentrations.[3] IV infusions of 0.02 or 0.04 mg/kg diluted in 5% dextrose (given over 20-50 minutes) have also been effective.[24] The onset of serum calcium concentration decline is slower with bisphosphonate therapy (concentrations begin to decline in 2 days and reach a nadir in 7 days); thus calcitonin therapy or other interventions may be necessary if more rapid serum calcium reduction is required.[22] Duration of normocalcemia after treatment is variable and dependent on the severity and treatment response of the underlying malignancy, but usually does not exceed 2 to 3 weeks.

Adverse Medication Reactions

Fever is a common adverse medication reaction of IV bisphosphonate therapy. The safety of continuous bisphosphonate therapy in treating hypercalcemia of malignancy is unclear; however, zoledronic acid has been associated with atrial fibrillation.[25] Kidney function monitoring (eg, serum creatinine) is advised with the use of bisphosphonates, as kidney function declines and acute tubular necrosis occurs rarely.[26,27] It is advisable to evaluate serum creatinine within a week after the infusion and just prior to the next scheduled dose.[22] Osteonecrosis of the jaw is a rare, but serious adverse medication reaction. With osteonecrosis of the jaw, there is an area of exposed bone in the maxillofacial or mandibular region that does not heal within 8 weeks after diagnosis.[22] Higher potency bisphosphonates and longer durations of therapy are associated with increased risk.[28]

Denosumab

Pharmacology

Denosumab is a monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) ligand (RANKL), a principal mediator of osteoclast survival. Denosumab is FDA approved for the treatment of patients with hypercalcemia of malignancy.[3] The medication is effective in treatment of patients with hypercalcemia of malignancy (with or without bone metastases) who are refractory to IV bisphosphonate therapy, that is, their corrected serum calcium remains above 12.5 mg/dL (3.13 mmol/L) after more than 7 days of therapy.[3] Denosumab has also been reported to successfully treat hypercalcemia after successful stem cell transplantation and restitution of osteoclast function in patients with osteopetrosis, a heritable disorder associated with defective osteoclast function.[2,29]

Adverse Medication Reactions

Denosumab has been associated with osteonecrosis of the jaw.[30] Although advanced kidney disease has not been shown to affect the pharmacodynamics and pharmacokinetics of denosumab, severe, symptomatic hypocalcemia has been reported in CKD patients receiving the medication.[31] Close monitoring of serum calcium is recommended for patients with creatinine clearance (CrCl) < 30 mL/min (0.5 mL/s).[22] This may be due to induction of a hungry bone-like syndrome and warrants careful monitoring.[32]

Corticosteroids

Prednisone or an equivalent agent is usually effective in the treatment of hypercalcemia resulting from multiple myeloma, leukemia, lymphoma, sarcoidosis, and hypervitaminoses A and D.[9,33,34] Corticosteroids are effective because they reduce GI calcium absorption.[34] Corticosteroids may also prevent tachyphylaxis to salmon calcitonin.[35] Daily doses of 40 to 60 mg of prednisone or the equivalent have effectively normalized serum calcium values within 3 to 5 days followed by a reduction in urinary calcium excretion within 7 to 10 days. The disadvantages of corticosteroid therapy are its relatively slow onset of action and the potential for diabetes mellitus, osteoporosis, and increased susceptibility to infection.[36]

Cinacalcet

The calcimimetic agent cinacalcet is approved for management of parathyroid carcinoma, primary hyperparathyroidism where parathyroidectomy is indicated but cannot be undertaken, and secondary hyperparathyroidism in patients with CKD on dialysis.[3,37] Cinacalcet is an allosteric modulator of the CaSr, and increases the sensitivity for receptor activation by extracellular calcium. This results in reduced PTH and serum calcium concentrations.[3,37] Cinacalcet administered at a starting dose of 30 mg orally twice daily has been used for the treatment of hypercalcemia secondary to parathyroid carcinoma. The dosage is titrated every 2 to 4 weeks in 30 mg increments until the desired serum calcium concentration is achieved. The maximum approved dosage is 90 mg four times daily.[3] Hypocalcemia is a common adverse medication reaction and patients with specific CaSR polymorphisms may be particularly susceptible.[37] Patients should have serum calcium measured within 1 week after starting or increasing the dose of this agent. The role of cinacalcet in the management of nephrolithiasis is still controversial, but it has shown benefits in patients with primary hyperparathyroidism.[38] Etelcalcetide is the first IV calcimimetic that is structurally different from cinacalcet but also acts as an allosteric modulator of the CaSR. Etelcalcetide is only approved to treat secondary hyperparathyroidism in hemodialysis patients (see Chapter 64).[39]

Pharmacoeconomic Considerations

Corticosteroids are inexpensive for treatment of asymptomatic hypercalcemia from a pharmacoeconomic standpoint; however, the low cost of the medication may be offset by the multitude of long-term adverse medication reactions and potential need for additional treatment. Calcitonin is only suitable for short-term therapy and thus the long-term pharmacoeconomic benefits are unknown. Use of bisphosphonates for the management of bone metastases of malignancy is associated with lower morbidity and health gains (quality of life) well below the typical cost-effectiveness threshold.[40] Due to calcitonin's faster onset of action, it may be added to bisphosphonate treatment for rapid serum calcium reduction. However, combination treatment with a bisphosphonate plus calcitonin likely results in similar outcomes and higher costs for moderate-to-severe hypercalcemia of malignancy.[41] The introduction of denosumab and its demonstrated efficacy in preventing and delaying skeletal-related adverse medication reactions while reducing hypocalcemia have prompted questions regarding its cost-effectiveness.[40] Although denosumab is associated with additional health gains compared to zoledronic acid, it may not offer economic advantages.[40] Additional considerations for choice of therapy include co-pay costs and patient assistance program availability for these agents.[42]

Nephrolithiasis from Chronic Hypercalcemia and Hypercalciuria

Patients who develop nephrolithiasis from hypercalciuria are most often treated with sodium citrate to prevent stone formation, thiazide diuretics to decrease urinary calcium excretion, or shock wave lithotripsy (Table 69-3). There are multiple approaches to treating and preventing future nephrolithiasis issues which include stone removal or disintegration, using medications to dissolve or prevent stone formation as well as dietary interventions to prevent stone formation.[18] Procedures such as shockwave lithotripsy are effective in disintegrating stones and subsequently allowing for their urinary removal; however, the procedure is painful and expensive. Urinary alkalinizing agents such as potassium or sodium citrate prevent growth of stone diameter, increasing the likelihood of spontaneous passage. These agents are available in liquid form, but must be taken consistently multiple times per day to maintain an alkaline urine.[15] Thiazide diuretics decrease urinary calcium excretion and reduce the potential for crystal formation and are commonly used for prevention.[18] Other agents such as calcium binding resins, natural plant extracts (*Phyllanthus niruri),* and reduction of dietary calcium offer little benefit.

TABLE 69-3

Treatment of Nephrolithiasis Associated with Chronic Hypercalcemia and Hypercalciuria

Intervention	**Indications**	**Comments**
Extracorporeal Shock Wave Lithotripsy		
Uses sound waves to break up stones, which then can pass spontaneously	Obstruction of the urinary tract, especially with stones >5 mm	Consider adjunctive use of potassium citrate to inhibit aggregation of residual fragments
Prevention of Stone Formation		
Alkalinizing agents	Prevention; Treatment for nonemergent active stones	Potassium citrate is preferred over sodium citrate as it decreases urinary calcium, inhibits calcium oxalate precipitation, and increases urinary citrate more
Potassium citrate PO 20 mEq three times daily or 30 mEq twice daily		
Sodium citrate PO 20-30 mEq twice daily		
Decrease Urinary Calcium Excretion		
Thiazide diuretics	Prevention	Medication of choice in patients with low bone density
Hydrochlorothiazide PO 50 mg daily		
Indapamide PO 2.5 mg daily		
Chlorthalidone PO 25 mg daily		
Binding Intestinal Calcium		
Cellulose sodium phosphate PO 10 g daily in three divided doses with meals	Prevention for those with absorptive hypercalciuria	Restrict dietary intake of oxalate-containing foods, concomitant magnesium therapy recommended, alternative to thiazides if intolerant or ineffective, initial dose dependent on urinary calcium excretion, monitor bone density
Inhibition of Crystal Formation		
Phyllanthus niruri plant extract PO 2 g daily	Prevention, after shock wave lithotripsy	Commercial preparations with *P. niruri* as the sole ingredient can be difficult to obtain, variable dosages reported

Low-Calcium Diet		
Less than 400 mg/day	Prevention	Monitor bone density prior to and periodically during treatment, limit oxalate restriction, can increase hyperoxaluria, high calcium intake may actually be more beneficial

HYPOCALCEMIA

③ Hypocalcemia (total serum calcium less than 8.6 mg/dL [2.15 mmol/L] or ionized calcium less than 4.4 mg/dL [1.10 mmol/L]) occurs infrequently in the outpatient setting and is most common in older adults, malnourished patients, and those who have received sodium phosphate as a bowel preparation agent.

Epidemiology

Hypocalcemia occurs in 15% to 88% of adult hospitalized patients.[1] Emergent treatment of hypocalcemia is rarely warranted unless life-threatening symptoms are present (eg, frank tetany or seizures).

Pathophysiology

Hypocalcemia is the result of alterations in the effect of PTH and vitamin D on the bone, gut, and kidney (see Fig. 69-1). The primary causes of hypocalcemia are vitamin D deficiency and postoperative hypoparathyroidism. Other causes include magnesium deficiency, critical illness, medications, hypoalbuminemia, blood transfusions, peripheral blood progenitor cell harvesting, tumor lysis syndrome, and mutations in the CaSr.[37,43–47] PTH concentrations are elevated in conditions of hypocalcemia, except hypoparathyroidism and hypomagnesemia.[48]

Vitamin D Deficiency

Vitamin D and its metabolites play an important role in the maintenance of extracellular calcium concentrations and in normal skeletal structure and mineralization. Vitamin D is necessary for the optimal absorption of calcium and phosphorus. On a worldwide basis, the most common cause of chronic hypocalcemia is nutritional vitamin D deficiency. In malnourished populations, manifestations include rickets and osteomalacia. Nutritional vitamin D deficiency is uncommon in Western societies because of the fortification of milk with ergocalciferol. The most common cause of vitamin D deficiency in Western societies is GI disease.[9] Gastric surgery, chronic pancreatitis, small-bowel disease, intestinal resection, and bypass surgery are associated with decreased concentrations of vitamin D and its metabolites.[9] Vitamin D replacement therapy might need to be administered by the IV route if poor oral bioavailability is noted. Decreased production of 1,25-dihydroxyvitamin D_3 can occur as a result of a hereditary defect leading to vitamin D-dependent rickets.[48] Polymorphisms of the vitamin D receptor have been identified, and these genetic variations can contribute to increased risk of rickets associated with vitamin D and calcium-deficient diets.[49] It also can occur secondary to CKD if there is insufficient production of the 1-α-hydroxylase enzyme for the production of the 1,25-dihydroxyvitamin D_3. Treatment of hypocalcemia associated with CKD is reviewed in Chapter 62.

Hypoparathyroidism

Hypoparathyroidism can be caused by autoimmune disease, congenital defects, or iatrogenically by inadvertent removal of some or all of the parathyroid glands during thyroidectomy or from damage with radiation therapy. Surgery is the most common cause of chronic hypoparathyroidism, but only occurs in about 3% of patients who have undergone total thyroidectomy.[48] Chronic hypoparathyroidism that persists for more than 6 months may insidiously lead to hypocalcemia and thus most patients remain asymptomatic.[48] The chronic hypocalcemia may ultimately present as visual impairment secondary to cataracts.[50]

Hungry Bone Syndrome

An acute, symptomatic rapid fall in total serum calcium concentration (to values less than 7 mg/dL [1.75 mmol/L]) is common in patients who have recently had a parathyroidectomy or thyroidectomy. Hypocalcemia in these postsurgical patients is generally transient in nature.[48] The “hungry bone syndrome” is a condition of profound hypocalcemia whereby the bone avidly incorporates calcium and phosphorus from the blood in an attempt to recalcify bone.[51] Serum calcium concentrations should be monitored every 6 hours during the 24 to 48 hours following such surgeries, and pharmacologic doses of calcium can be necessary to prevent or minimize the decrease in serum calcium.

Hypomagnesemia

Hypomagnesemia of any cause can be associated with severe symptomatic hypocalcemia that is unresponsive to calcium replacement therapy (see Chapter 70). Reduced serum magnesium concentrations can impair PTH secretion and induce resistance of target organs to the actions of PTH.[48] Normalization of serum calcium concentrations in these patients is thus dependent on appropriate replacement of magnesium.

Critical Illness

During critical illness or postoperatively, hypocalcemia is common but usually mild. It is hypothesized that cytokines impair PTH secretion, decrease production of 1,25-dihydroxyvitamin D_3, and cause PTH end-organ resistance.[48]

Medication-Induced Hypocalcemia

Medication-induced hypocalcemia has been reported due to chelation of calcium (eg, oral sodium phosphate solutions, ethylenediaminetetraacetate, foscarnet), increased enzymatic processing of vitamin D (eg, phenobarbital, phenytoin, ketoconazole), decreased PTH sensitivity (eg, calcitonin), increased sensitivity of the CaSr (eg, cinacalcet), increased excretion of calcium (eg, furosemide), blocked bone resorption (eg, denosumab, bisphosphonates, fluoride), and induction of hypomagnesemia (eg, aminoglycosides).[31,48,52,53]

Chelating agents in blood (citrate) and in radiographic contrast media (ethylenediaminetetraacetate) can cause transient hypocalcemia.[43,44,48] Concentrated citrate is often used in hemodialysis catheter locks and to anticoagulate the dialysis circuit during continuous kidney replacement therapy.[54] Symptomatic hypocalcemia has been reported in patients exposed to citrate solutions, which is related to both the concentration of the citrate solution and capacity to metabolize citrate (ie, impaired metabolism with severe liver failure and tissue hypoperfusion).[55] Injection of citrate solutions greater than the volume of the dead space of the catheter lumen or accidental injection of citrate catheter lock solutions that are not intended for systemic administration has been associated with serious cardiovascular problems such as hypotension or cardiac arrest.[56] Oral phosphorus therapy, commonly used to treat patients with malabsorption syndromes caused by GI diseases, can also result in hypocalcemia by chelation.

The anticonvulsants phenobarbital and phenytoin cause hypocalcemia by increasing catabolism of vitamin D and thereby impairing calcium release from bone and reducing intestinal calcium absorption.[43] By decreasing PTH sensitivity, calcitonin can lead to hypocalcemia.[48] Cinacalcet increases the sensitivity of the CaSr potentially inducing hypocalcemia.[48] Loop diuretics such as furosemide can induce hypocalcemia by increasing calcium excretion.[48] Denosumab and bisphosphonates block bone resorption and can lead to hypocalcemia, especially in the presence of vitamin D deficiency, insufficient calcium intake, or PTH imbalance.[48] Medications that cause hypomagnesemia (eg, aminoglycosides, amphotericin B, cyclosporine, diuretics, foscarnet, and cisplatin) are also associated with an increased risk of hypocalcemia.[57]

Clinical Presentation: Hypocalcemia

CLINICAL PRESENTATION: Hypocalcemia

General

- Acute hypocalcemia may result in rapid decreases in serum ionized calcium. Parathyroidectomy and thyroidectomy are also associated with a rapid reduction in serum calcium. In chronic hypocalcemia, vitamin D deficiency should be considered.

Symptoms

- The symptoms of hypocalcemia include tetany, paresthesia, muscle cramps, and laryngeal spasms. Chronic hypocalcemia is usually associated with depression, anxiety, memory loss, and confusion.

Signs

- Neurologic: The hallmark of acute hypocalcemia is tetany, which is characterized by neuromuscular irritability including seizure potential. Extrapyramidal disorders, mainly parkinsonism but also dystonia, hemiballismus, choreoathetosis, and oculogyric crises occur in 5% to 10% of patients with idiopathic hypoparathyroidism. Chvostek and/or Trousseau signs can be elicited during physical examination.
- Dermatologic: The skin can be dry, puffy, and coarse. Other dermatologic manifestations can include hyperpigmentation, dermatitis, eczema, and psoriasis. Hair and skin signs including coarse, brittle, and sparse hair with patchy alopecia and brittle nails can also appear.
- Ophthalmologic: Cataract development has been reported to occur with hypocalcemia.
- Dental manifestations: These are usually associated with the presence of chronic hypocalcemia in early development. Signs include dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth.
- Cardiovascular: Hypotension, decreased myocardial performance, and heart failure have been reported. A prolonged QT interval, arrhythmias, and bradycardia can also occur but are more common with acute or severe hypocalcemia.
- GI: Steatorrhea can be associated with chronic hypocalcemia.
- Musculoskeletal: Myopathy has been reported.
- Endocrine: Hypocalcemia alone can impair insulin release. In addition, idiopathic hypoparathyroidism can be associated with polyglandular autoimmune syndromes.

Laboratory Tests

- Serum calcium concentrations of less than 8.6 mg/dL (2.15 mmol/L) are considered to represent hypocalcemia if ionized calcium values are also less than 4.4 mg/dL (1.1 mmol/L).

The clinical manifestations of hypocalcemia are quite variable. The more acute the decrease in ionized calcium concentration, the more likely the patient will develop symptoms.[48] Increases in plasma pH enhance the binding of calcium to albumin and thus alkalosis can result in rapid decreases in ionized calcium. Concomitant hypomagnesemia, hypokalemia, hyponatremia, and additive adverse medications reactions also increase the likelihood of symptomatic presentation.

Hypocalcemia can manifest as neuromuscular, central nervous system (CNS), dermatologic, and cardiac sequelae.[1] Acute hypocalcemia is more likely to manifest as neuromuscular (paresthesia, muscle cramps, tetany, and laryngeal spasm), and cardiovascular symptoms, whereas chronic hypocalcemia often presents as CNS (eg, depression, anxiety, memory loss, confusion, hallucinations, tonic–clonic seizures) and dermatologic (eg, hair loss, grooved and brittle nails, eczema) symptoms.[43] The hallmark sign of acute hypocalcemia is tetany caused by enhanced peripheral neuromuscular irritability.[1] Tetany manifests as paresthesia around the mouth and in the extremities, muscle spasms and cramps, carpopedal (hands and feet) spasms, and rarely as laryngospasm and bronchospasm.[9] Chvostek and/or Trousseau signs can be elicited during physical examination.[48]

Chvostek sign is elicited by tapping the facial nerve anterior to the ear and eliciting twitching of facial muscles. The sensitivity and specificity of Chvostek sign for hypocalcemia are limited; a positive Chvostek sign is observed in 25% of healthy individuals and 29% of patients with hypocalcemia are negative.[48] Trousseau sign is elicited by inflating a blood pressure cuff above systolic blood pressure for 3 minutes and observing whether a carpal spasm is induced. With only 1% of healthy individuals with a positive Trousseau, this sign has greater specificity for hypocalcemia.[48]

The cardiovascular manifestations of hypocalcemia result in ECG changes characterized by a prolonged QT interval and symptoms of decreased myocardial contractility often associated with heart failure.[43] Both acute and chronic hypocalcemia can result in a reversible syndrome characterized by acute myocardial failure or refractory heart failure. Other cardiovascular manifestations include arrhythmias, bradycardia, and hypotension that are unresponsive to fluid and vasopressor administration.[43]

Treatment

Desired Outcome

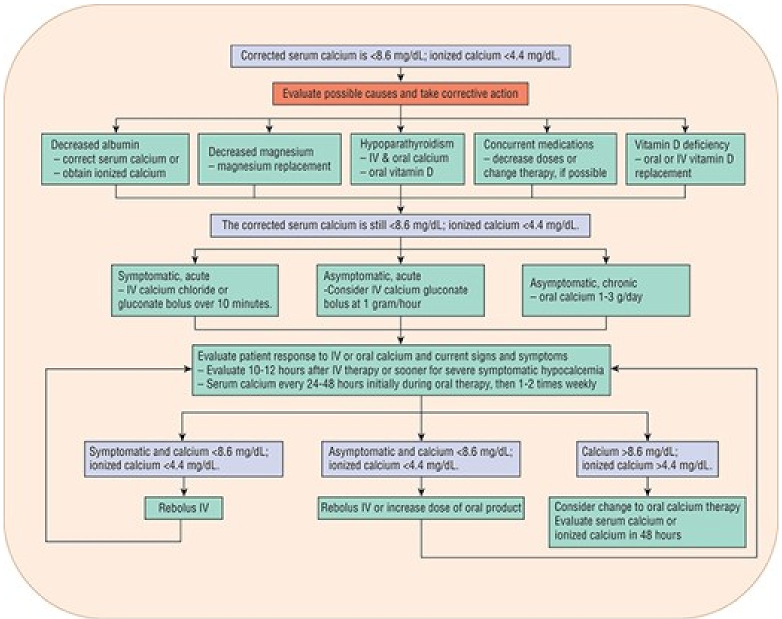
④ The goals of therapy for patients with normal kidney function are the resolution of signs and symptoms of hypocalcemia, restoration of normocalcemia, management of associated electrolyte abnormalities, and treatment of the underlying cause of hypocalcemia. The goals for patients with CKD are different and are discussed in Chapter 62. Asymptomatic hypocalcemia associated with hypoalbuminemia requires no treatment because ionized (biologically active) plasma calcium concentrations are normal. Treatment of hypocalcemia is dependent on identification of the pathogenesis of the underlying disorder, acuteness of onset, and presence and severity of symptoms.

Pharmacologic Therapy

Treatment of hypocalcemia is driven by acuity of onset and how significant the ionized calcium is below the normal range. The first approach to treatment is to evaluate causes that will dictate corrective action. Acute symptomatic hypocalcemia will nearly always require parenteral administration of soluble calcium salts (Fig. 69-3).

FIGURE 69-3

Hypocalcemia diagnostic and treatment algorithm. Serum calcium of 8.6 mg/dL is equivalent to 2.15 mmol/L and 4.4 mg/dL is equivalent to 1.10 mmol/L).



Corrected serum calcium is <8.6 mg/dL; ionized calcium <4.4 mg/dL.
Evaluate possible causes and take corrective action
Decreased albumin – correct serum calcium or – obtain ionized calcium
Decreased magnesium – magnesium replacement
Hypoparathyroidism – IV & oral calcium – oral vitamin D
Concurrent medications – decrease doses or change therapy, if possible
Vitamin D deficiency – oral or IV vitamin D replacement
The corrected serum calcium is still <8.6 mg/dL; ionized calcium <4.4 mg/dL.
Symptomatic, acute – IV calcium chloride or gluconate bolus over 10 minutes.
Asymptomatic, acute -Consider IV calcium gluconate bolus at 1 gram/hour
Asymptomatic, chronic – oral calcium 1-3 g/day
Evaluate patient response to IV or oral calcium and current signs and symptoms
– Evaluate 10-12 hours after IV therapy or sooner for severe symptomatic hypocalcemia
– Serum calcium every 24-48 hours initially during oral therapy, then 1-2 times weekly
Symptomatic and calcium <8.6 mg/dL; ionized calcium <4.4 mg/dL.
Asymptomatic and calcium <8.6 mg/dL; ionized calcium <4.4 mg/dL.
Calcium >8.6 mg/dL; ionized calcium >4.4 mg/dL.
Rebolus IV
Rebolus IV or increase dose of oral product
Consider change to oral calcium therapy Evaluate serum calcium or ionized calcium in 48 hours

Acute Treatment

The initial therapeutic intervention for patients with severe, symptomatic hypocalcemia (ionized calcium < 4 mg/dL [1 mmol/L]) is to administer 0.5 to 1 g of calcium chloride (1 g calcium chloride = 13.6 mEq calcium) or up to 3 g of calcium gluconate (1 g calcium gluconate = 4.56 mEq calcium) IV slowly over 10 minutes.[1] The treatment of asymptomatic hypocalcemia is controversial, but many practitioners will supplement calcium to avoid negative consequences of hypocalcemia and progression to clinical manifestations.[1] For mild-moderate asymptomatic hypocalcemia (ionized calcium 1-4.48 mg/dL or 1-1.12 mmol/L), 1 to 2 g IV calcium gluconate is recommended, and in the case of severe, asymptomatic hypocalcemia, up to 3 g IV calcium gluconate is indicated as in symptomatic patients.[1] For critically ill patients who are asymptomatic with a serum total calcium less than 7 mg/dL (1.75 mmol/L), 1 to 2 g IV calcium gluconate may be empirically administered with follow-up measurement of ionized calcium.[1] In non-emergent, asymptomatic cases, calcium retention and safety are optimized by infusing calcium gluconate at a rate of 1 g/hr.[1] Since calcium chloride delivers three times more elemental calcium than an equivalent amount of calcium gluconate, clinicians must carefully review dosing to ensure medication errors do not occur. Calcium gluconate is generally preferred over calcium chloride for peripheral venous administration because calcium gluconate is less irritating to veins. To prevent tissue necrosis, calcium chloride should be administered via central venous access. Calcium should not be infused at a rate greater than 60 mg elemental calcium per minute because severe cardiac dysfunction, including ventricular fibrillation, can result, thus ECG monitoring is recommended.[57] IV calcium administration should be used with caution in patients receiving digitalis glycosides because of the possibility of bradycardia or atrioventricular (AV) block.[50] In severe hypokalemia, an acute rise in serum calcium from IV calcium administration can result in cardiac arrhythmias. Bolus doses of calcium are only effective for 1 to 2 hours; therefore, repeat doses should be given hourly as needed until severe, symptomatic patients are stabilized.[1,57] Ionized calcium should be reevaluated approximately 10 to 12 hours after supplementation or sooner for severe, symptomatic hypocalcemia.[1] Calcium should not be added to bicarbonate- or phosphate-containing solutions or infused in the same IV line because of the possibility of precipitation.[57]

Chronic Treatment

Once acute hypocalcemia is corrected by parenteral administration, further treatment modalities should be individualized according to the cause of hypocalcemia. If hypomagnesemia is present, then magnesium supplementation is indicated until concentrations normalize, which will promote successful calcium supplementation regardless of route (see Chapter 70). Hypocalcemia secondary to hungry bone syndrome following parathyroidectomy has been attenuated by pretreatment with bisphosphonates, especially with longer duration use and normalization of alkaline phosphatase prior to surgery.[58] Asymptomatic and chronic hypocalcemia associated with hypoparathyroidism and vitamin D-deficient states can be managed by oral calcium and vitamin D supplementation. Therapy is initiated with 1 to 3 g/day of elemental calcium.[57] Average maintenance doses range from 2 to 8 g of elemental calcium per day in divided doses. If serum calcium does not normalize, a vitamin D supplement may need to be added. In patients with achlorhydria a solution of 10% (1-30 mL) calcium chloride orally every 8 hours can raise serum calcium.[57] Treatment of chronic hypoparathyroidism with PTH formulations such as teriparatide has been shown to better maintain serum calcium concentrations and normalize urinary calcium.[59]

Treatment of chronic asymptomatic hypocalcemia associated with vitamin D-deficient states should be individualized. The optimal 25-hydroxyvitamin D concentration is controversial, but the Endocrine Society defines vitamin D sufficiency as a concentration of at least 30 ng/mL (75 nmol/L).[60] In patients with malabsorption, vitamin D requirements vary markedly, and large doses can be required. In contrast, vitamin D deficiency associated with anticonvulsant medication can be corrected with smaller doses of vitamin D. The usual oral dose of ergocalciferol is 50,000 international units once weekly for 8 weeks followed by decreased maintenance dosing as needed to achieve the goal 25-hydroxyvitamin D concentration.[60] The treatment of vitamin D deficiency associated with CKD generally requires the administration of 1,25-dihydroxyvitamin D_3 or another synthetic vitamin D_2 analog such as paricalcitol or doxercalciferol (see Chapter 61). Patients who have reduced 25-hydroxylase activity (eg, hepatic disease) can also require treatment with calcitriol (1,25-dihydroxyvitamin D_3). Oral doses of 1,25-dihydroxyvitamin D_3 usually range from 0.5 to 2 μg daily. Vitamin D_3 (cholecalciferol) may be more efficacious at raising serum 25-hydroxyvitamin D concentrations compared with plant source vitamin D_2 (ergocalciferol). However, higher loading and maintenance doses of cholecalciferol may be required to maintain serum 25-hydroxyvitamin D concentrations. In selected cases, increasing calcium ingestion can be required if vitamin D replacement alone is ineffective in returning serum calcium concentrations to normal.

Adverse Medication Reactions

Adverse medication reactions of oral calcium and vitamin D supplementation include hypercalcemia and hypercalciuria, especially in patients with hypoparathyroidism, in whom the renal calcium-sparing effect of PTH is absent. Hypercalciuria can increase the risk of calcium stone formation and nephrolithiasis in susceptible patients. One maneuver to help prevent calcium stones is to maintain the urine calcium excretion below 300 mg/day. Intermittently monitoring of 24-hour urine collections for total calcium excretion can help minimize the occurrence of hypercalciuria. The addition of thiazide diuretics for patients at risk for stone formation can increase tubular calcium reabsorption and reduction of vitamin D requirements (see Table 69-3).[57]

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Inorganic phosphorus in the form of phosphate is an essential element in phospholipid cell membranes, nucleic acids, and phosphoproteins, which are required for mitochondrial function.[61] Phosphorus regulates the intermediary metabolism of carbohydrates, fats, and proteins. Phosphorus also regulates enzymatic reactions including glycolysis, ammoniagenesis, and the 1-hydroxylation of 25-hydroxyvitamin D_3.[61] In addition, phosphorus is required for the generation of 2,3-diphosphoglycerate (2,3-DPG) in red blood cells, which is required for normal oxygen–hemoglobin dissociation and delivery of oxygen to the tissues.[61] Phosphorus is the source of the high-energy bonds of adenosine triphosphate (ATP), thus fueling a wide variety of physiologic processes, including muscle contractility, electrolyte transport, neurologic function, and other important biochemical reactions.[61] Considering its diverse biologic importance, it is not difficult to appreciate the clinical implications of disorders of phosphorus homeostasis.

Phosphate, the major intracellular anion, is present in living organisms mainly as organic phosphate esters such as 2,3-DPG, adenosine, guanosine triphosphate, and fructose 1,6-diphosphate.[61] Only a small fraction of intracellular phosphorus exists as inorganic phosphate; however, this fraction is critical because it is the source from which ATP is resynthesized.[61] The majority of inorganic phosphate is located in the extracellular space where it is the prime determinant of intracellular phosphate; thus, small increments in the organic phosphate concentrations can profoundly alter both the extracellular and intracellular phosphate concentrations. Metabolic disturbances (acidosis, alkalosis, and ketoacidosis), hydrogen ion shifts, and hormones (PTH, calcitonin, cortisol, and vitamin D) all can cause transcellular shifts in phosphorus concentrations. Because of these phenomena, the serum phosphorus concentration does not accurately reflect total body stores.[62]

The typical Western diet provides a daily intake of 800 to 1,600 mg of phosphorus. Approximately 60% to 80% of this is absorbed in the GI tract by passive and active transport (vitamin D-mediated). PTH, 1,25-dihydroxyvitamin D_3, and low-phosphate diets mediate increased absorption. Decreased absorption occurs under conditions of increased dietary intake of phosphorus and magnesium, glucocorticoid therapy, and hypothyroidism. The normal serum phosphorus concentration in adults is 2.7 to 4.5 mg/dL (0.87-1.45 mmol/L) and for children younger than 12 years it is 4 to 5.6 mg/dL (1.29-1.81 mmol/L). Influx via the GI tract and bone and tubular reabsorption by the kidney are the most important regulators of steady-state serum phosphorus concentrations. Renal excretion of phosphorus is a two-step process: glomerular filtration and proximal tubular reabsorption by passive transport coupled to sodium. Under normal conditions, 85% to 90% of filtered phosphate is reabsorbed, the majority in the early proximal tubule. Renal tubular reabsorption of phosphate is inhibited by PTH and 1,25-dihydroxyvitamin D_3.[62] Fibroblast growth factor 23 (FGF23) is a key regulator of phosphate homeostasis.[63] FGF23 acts principally to decrease tubular reabsorption of phosphate and inhibit 1-α-hydroxylase, thereby reducing the concentration of active vitamin D. FGF23-mediated receptor activation requires klotho, a transmembrane protein. The tissue specificity for FGF23 effects is defined by klotho–FGF23 coexpression. Conversely, phosphate reabsorption in the renal tubule is increased by growth hormone, insulin, and insulin-like growth factor 1.[61] Internal phosphorus balance (ie, transcellular phosphate distribution) is also of importance in the maintenance of normal serum phosphate. The serum phosphate concentration can vary by as much as 2 mg/dL (0.65 mmol/L) throughout the day, primarily as the result of changes in carbohydrate intake, insulin secretion, and diurnal variation.[61]

HYPERPHOSPHATEMIA

Hyperphosphatemia typically results from either CKD, AKI, or endogenous intracellular phosphate release. Hyperphosphatemia occurs frequently in patients with AKI and is a nearly universal finding in those with advanced CKD (eg, stages 4 and 5). Tumor lysis syndrome, a complication of chemotherapy associated with massive lysis of cells and release of intracellular contents is also associated with hyperphosphatemia. The incidence of tumor lysis syndrome is highest among patients treated for acute lymphoblastic leukemia, acute myeloid leukemia and Burkitt's lymphoma (see Chapter 155).[46] Other causes of hyperphosphatemia include hemolysis and rhabdomyolysis.

Pathophysiology

5 The most common cause of hyperphosphatemia is a reduction in renal tubular excretion of phosphate despite elevations in PTH and FGF-23 when GFR is markedly impaired (eg, GFR less than 25 mL/min/1.73 m^2 [0.24 mL/s/m^2]).[62,64] Retention of phosphate decreases vitamin D synthesis and induces hypocalcemia, which leads to an increase in PTH, a finding that can be seen in those with stage 2 to 5 CKD. This physiologic response inhibits further tubular reabsorption of phosphorus as the kidney attempts to correct hyperphosphatemia and normalize serum calcium concentrations. Patients with excessive exogenous phosphate administration or who experience massive tissue breakdown or cell lysis in the setting of AKI can rapidly develop moderate-to-severe hyperphosphatemia (serum phosphate more than 6.5 mg/dL [2.10 mmol/L]).[62] Severe hyperphosphatemia (serum phosphate more than 7 mg/dL [2.26 mmol/L]) is commonly encountered in patients with CKD, especially those with GFRs less than 15 mL/min/1.73 m^2 (0.14 mL/s/m^2) (see Chapter 61).

Hyperphosphatemia caused by an increase in renal tubular reabsorption associated with hypoparathyroidism and associated decreases in PTH, is usually less severe than that observed in patients with advanced kidney disease or excessive exogenous or endogenous introduction of phosphate into the ECF. Acromegaly (mediated by growth hormone) and thyrotoxicosis (mediated by catecholamines) can also cause hyperphosphatemia by increasing tubular phosphate reabsorption.

Exogenous Phosphate Loads

Iatrogenic causes of hyperphosphatemia have been widely reported, and clinicians should be aware of the phosphorus content of IV, oral, and rectally administered products.[65] Although less-well recognized, oral and rectal administration of phosphate-containing solutions such as sodium phosphate (Fleet® Phospho-Soda) can also result in severe and life-threatening hyperphosphatemia, especially in patients with moderate-to-severe CKD.[53,65] The risk of mortality is dependent on the amount of phosphorus absorbed from the administered product; however, fatalities have occurred at low phosphate concentrations.[65] Acute phosphate nephropathy and kidney failure have also been reported with the use of oral sodium phosphate bowel preparations. The FDA issued a safety warning regarding the use of these products in patients at risk (ie, older adults, patients with CKD) or on medications known to affect kidney hemodynamics (eg, diuretics, nonsteroidal anti-inflammatory drugs [NSAIDs], or renin–angiotensin–aldosterone system inhibitors).[66] Acute phosphorus poisoning as a result of ingestion of laundry detergents is a rare and often unrecognized cause of elevated phosphate concentrations.

Rapid Tissue Catabolism

Any disorder that results in necrosis of skeletal muscle (ie, rhabdomyolysis) can generate the release of large amounts of intracellular phosphate into the systemic circulation. This condition is frequently associated with AKI (see Chapter 61) and thus severe hyperphosphatemia can develop because of increased endogenous phosphate release coupled with the impaired renal excretion because phosphaturic hormones (eg, PTH, FGF23) become ineffective. Bowel infarction, malignant hyperthermia, and severe hemolysis are also conditions that can increase endogenous release of phosphate.

Moderate hyperphosphatemia is also commonly observed in patients undergoing treatment for acute leukemia and lymphomas.[46] Chemotherapeutic treatment of acute lymphoblastic leukemia can result in the release of large amounts of phosphate into the systemic circulation secondary to lysis of lymphoblasts. Initiation of chemotherapy for Burkitt lymphoma results in tumor lysis syndrome, a rapid lysis of malignant cells that results in hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia.[46]

Acid–Base Disorders

Lactic acidosis and diabetic ketoacidosis (DKA) can trigger the transcellular shift of endogenous intracellular phosphate into the extracellular space and thereby dramatically increases serum phosphorus concentrations.[67] After the institution of treatment, serum phosphate concentrations should be checked hourly as they can decrease rapidly, and patients can ultimately develop hypophosphatemia.

Clinical Presentation: Hyperphosphatemia

CLINICAL PRESENTATION: Hyperphosphatemia

General

- Serum phosphate concentration is primarily determined by the ability of the kidneys to reabsorb phosphate; therefore, hyperphosphatemia is uncommon in patients with normal kidney function.

Symptoms

- Acute symptoms include GI disturbances, lethargy, obstruction of the urinary tract, and rarely seizures. Symptoms associated with chronic hyperphosphatemia include "red eye" and pruritus.

Signs

- The elevated calcium-phosphate product results in precipitation in arteries, joints, soft tissues, and the viscera. This can result in tissue necrosis, termed calciphylaxis or calcemic uremic arteriopathy.

Laboratory Tests

- Serum phosphate concentrations more than 4.5 mg/dL (1.45 mmol/L) represent hyperphosphatemia.

The severe acute onset of hyperphosphatemia can result in calcium and phosphate complexation and lead to the precipitation of calcium phosphate crystals in soft tissues, and within the kidney that can result in nephrolithiasis or obstructive uropathy. Extravascular calcification can result in band keratopathy, "red eye," pruritus, and periarticular calcification, especially in patients with CKD. In addition, soft-tissue calcifications in the conjunctiva, skin, heart, cornea, lung, gastric mucosa, and kidney have been observed, primarily in patients with CKD and chronic disordered mineral metabolism.[62] Extracellular phosphate can form insoluble nanoparticles with both calcium and fetuin-A which are referred to as calciprotein particles.[61] Calcium-phosphate crystals are likely to form in vivo when the product of the serum calcium and phosphate concentrations exceeds 50 to 60 mg^2/dL^2 (4-4.8 $mmol^2/L^2$). Serum phosphate concentrations greater than 6.5 mg/dL (2.10 mmol/L) have been independently associated with increased morbidity and mortality in patients on maintenance hemodialysis.[68] Other symptoms associated with moderate-to-severe hyperphosphatemia include nausea, vomiting, diarrhea, lethargy, and seizures. The major effects of long-term hyperphosphatemia are related to the development of hypocalcemia (caused by phosphate inhibition of renal 1-α-hydroxylase) and its related consequences, as well as vascular and organ damage resulting from the deposition of calcium-phosphate crystals. Hyperphosphatemia associated with CKD can result in renal osteodystrophy because of overproduction of PTH. This condition is discussed in detail in Chapter 62.

Treatment

Desired Outcome

Management of patients with acutely elevated serum phosphorus concentrations should be directed at avoiding GI and neurologic symptoms and preventing deposition in the urinary tract to avoid the development of AKI. The treatment of hyperphosphatemia is focused on returning serum phosphorus concentrations to the normal or near normal (for patients with CKD) range, with the goal to minimize the long-term cardiovascular consequences of calcium-phosphate deposition in the vasculature. The Kidney Disease Improving Global Outcomes (KDIGO) clinical practice guidelines suggest that for patients with CKD stages 3 to 5, serum phosphorus should be maintained in the normal range. In hemodialysis-dependent patients with stage 5 CKD, KDIGO suggests lowering elevated phosphorus concentrations toward the normal range (see Chapter 62).[69]

Pharmacologic Therapy

Severe symptomatic hyperphosphatemia manifesting as hypocalcemia and tetany may be treated by the IV administration of calcium. Although this can seem counterintuitive and many consider it controversial, for a patient with phosphate of 16 mg/dL (5.17 mmol/L) and calcium of 7 mg/dL (1.75

mmol/L), for example (the calcium–phosphorus product is 112 mg^2/dL^2 [9 $mmol^2/L^2$]), correction of severe hypocalcemia is of primary importance because of the critical nature of this disorder. If serum calcium concentrations are not critically low, the initial management strategy should include limitation of all exogenous sources of phosphate and efforts to block further absorption should be initiated. Hemodialysis can be initiated if the patient remains symptomatic despite these interventions.[57]

⑥ In general, the most effective way to treat nonemergent hyperphosphatemia is to decrease phosphate absorption from the GI tract by implementing phosphate-binding therapy and altering the dietary content of phosphate.[62] Phosphate binding agents containing divalent and trivalent cations (calcium, lanthanum, magnesium, iron, and aluminum), or sevelamer are the agents most frequently used in the prevention and treatment of hyperphosphatemia (see Chapter 62).[70] Long-term treatment with aluminum hydroxide and aluminum carbonate should be avoided because the use of these agents has been associated with anemia, CNS disorders, and bone disease.[70] Calcium and magnesium agents are available in oral suspension formulations, which can aid administration in acutely ill patients who are receiving enteral nutrition. The most frequent adverse medication reaction from phosphate-binding agents (especially calcium) is constipation. Typically, calcium salts are the preferred initial phosphate-binding agents except when there is concomitant hypercalcemia or evidence of vascular calcification. For long-term therapy with phosphate binders, it is recommended to avoid hypercalcemia and to limit use of calcium-based phosphate binders, and this may require additional non-calcium agents such as sevelamer.[69] Calcium-based phosphate binders may increase vascular calcification, but there is no difference in cardiovascular events for hyperphosphatemia treated with lanthanum carbonate versus calcium carbonate in patients undergoing hemodialysis.[71] The iron-based binders offer the potential advantage of enhancing iron absorption (ferric citrate coordination complex) or reduced pill burden (sucroferric oxyhydroxide).[72] Other mechanistic approaches are being evaluated to manage hyperphosphatemia. Tenapanor is an investigational drug that blocks paracellular absorption of phosphate in the GI tract and may eventually be FDA approved for hyperphosphatemia treatment in adult patients with CKD undergoing hemodialysis.[73]

HYPOPHOSPHATEMIA

Mild-to-moderate hypophosphatemia is usually asymptomatic and associated with serum phosphate concentrations of 1.5 to 2.7 mg/dL (0.48-0.87 mmol/L), whereas severe hypophosphatemia that is frequently symptomatic is correlated with serum phosphorus concentrations of less than 1.5 mg/dL (0.48 mmol/L).[1]

Incidence

Hypophosphatemia has been observed in approximately 1% to 3% of the laboratory screening panels of patients who have been admitted to a hospital.[74] The incidence in hospitalized critically ill patients is 18% to 28%.[74] Unlike its severe form, mild or moderate hypophosphatemia seldom causes recognizable signs and symptoms.[1]

Pathophysiology

⑦ Hypophosphatemia can be the result of decreased GI absorption, reduced tubular reabsorption, or extracellular to intracellular redistribution.[61] Although mild-to-moderate hypophosphatemia is common and can occur in inpatients and outpatients, severe hypophosphatemia is predominantly encountered in the acute care setting and can be associated with life-threatening symptoms, including seizures, coma, and rhabdomyolysis (Table 69-4).

TABLE 69-4

Conditions Associated with the Development of Hypophosphatemia

Decreased GI absorption
Phosphate-binding drugs
• Sucralfate

- Calcium carbonate
- Aluminum/magnesium antacids
- Sevelamer
- Lanthanum carbonate
- Ferric citrate
- Sucroferric oxyhydroxide
Decreased dietary phosphorus intake
Glucocorticoids
Vitamin D deficiency/resistance
Hyperparathyroidism
Chronic diarrhea
Steatorrhea
Reduced tubular reabsorption
Hyperparathyroidism (primary and secondary)
Elevated FGF23
Recovery from burns
Rickets
Malignant neoplasms
Fanconi syndrome
Acute volume expansion
Metabolic acidosis
Renal transplantation
Vitamin D deficiency and/or resistance
Diuretics

• Loop diuretics
• Thiazide diuretics
• Osmotic agents
• Carbonic anhydrase inhibitors (acetazolamide)
Glucocorticoids
Sodium bicarbonate
Internal redistribution
Refeeding syndrome
Nutrition support
Parathyroidectomy (hungry bone syndrome)
Alcohol use disorder
Respiratory alkalosis
Diabetic ketoacidosis (correction)
Dextrose solutions
Insulin
Catecholamines
Anabolic steroids
Glucagon
Calcitonin
Erythropoietin

Decreased GI Absorption

Phosphate-binding substances such as sucralfate, calcium carbonate, sevelamer, lanthanum carbonate, sucroferric oxyhydroxide, ferric citrate coordination complex, and aluminum- or magnesium-containing antacids have the potential to bind large amounts of phosphorus in the gut, thereby preventing absorption. If phosphate-binding agents are ingested on a chronic basis in conjunction with a dietary phosphorus deficiency, hypophosphatemia can result.[1] Patients who are receiving long-term phosphate-binding agents, those with peptic ulcer disease or CKD, and those who may be predisposed to moderate hypophosphatemia (eg, alcohol use disorder) are at highest risk for the development of severe hypophosphatemia. Hyperparathyroidism can cause hypophosphatemia as a result of decreased GI absorption of dietary phosphorus.

Decreased Tubular Reabsorption

Reduced tubular reabsorption of phosphate can occur in patients with hyperparathyroidism (primary and secondary) with normal kidney function and those with vitamin D deficiency or elevated FGF23 concentrations. Elevated PTH concentrations lead to an increase in serum calcium concentrations and decreased serum phosphate concentrations. Serum phosphorus is decreased as the result of a reduction in renal tubular reabsorption.[67] Recovery from extensive third-degree burns is associated with development of an anabolic state as stress levels decrease and nutritional therapies take effect as well as a marked diuretic phase associated with an impressive renal loss of phosphate.[75] Because phosphate is rapidly incorporated into the new cells, this can contribute to the severity of the hypophosphatemia. Medications that cause increased renal elimination of phosphate include diuretics (eg, loop diuretics, thiazide diuretics, osmotic diuretics), carbonic anhydrase inhibitors (eg, acetazolamide), glucocorticoids, and sodium bicarbonate.[1] The IV iron formulation ferric carboxymaltose has been associated with the development of hypophosphatemia in 51% of patients treated, and 13% of cases were severe (serum phosphorus less than 1 mg/dL [0.32 mmol/L]) and prolonged.[76] The mechanism is unclear, however, iron deficiency itself is associated with elevated FGF-23.[77]

Internal Redistribution

Rapid refeeding of malnourished patients with high-carbohydrate, high-calorie diets with inadequate amounts of supplemental phosphate can result in severe symptomatic hypophosphatemia. This phenomenon is especially prevalent in patients with other underlying risk factors for the development of hypophosphatemia, such as alcohol use disorder.[75] The etiology of severe hypophosphatemia associated with nutrition support can be separated into two phases: acute, rapid hypophosphatemia secondary to intracellular shifts of phosphate resulting from glucose-induced insulin secretion; and the gradual decrease in serum phosphate concentration over 5 to 10 days secondary to tissue repair in the presence of phosphate deprivation.[78] The development of severe hypophosphatemia secondary to nutrition support can be prevented by appropriate phosphate supplementation. Adult patients with normal kidney function receiving parenteral nutrition require approximately 10 -15 mmol of phosphorus per 1,000 kcal (2.4-3.6 mmol per 1000 kJ) (see Chapter 165).[1] The Recommended Dietary Allowance of phosphorus for healthy adults is provided in one liter of most enteral nutrition formulations (see Chapter 166).[1] In severely malnourished patients, the phosphorus requirements are higher with the initiation of nutrition support.[1] Phosphorus requirements are also typically increased in patients with critical illness, thermal injury, traumatic brain injury, and liver resection.[1] Transcellular shifts in phosphate also occur after parathyroidectomy, causing severe hypocalcemia and hypophosphatemia because of hungry bone syndrome (deposition of phosphate and calcium in the bone).

Severe and prolonged respiratory alkalosis (a result of hyperventilation, pain, anxiety, and sepsis) can cause hypophosphatemia.[74] Respiratory alkalosis is thought to contribute significantly to the hypophosphatemia observed during alcohol withdrawal syndrome.[62] Although patients with DKA may present with hyperphosphatemia, the initiation of therapy to correct it can cause serum phosphate concentrations to decrease rapidly as phosphate shifts back into the intracellular compartment. In addition, the acidosis associated with the DKA state can cause a decomposition of organic compounds inside the cell and a release of inorganic phosphate into the plasma and subsequently into the urine.[79] The combination of intracellular phosphate breakdown and the shift of phosphate into cells on initiation of treatment can lead to severe hypophosphatemia. Medications associated with transcellular shifts in phosphate include dextrose solutions, glucagon, insulin, catecholamines, calcitonin, erythropoietic agents, and anabolic steroids.

Patients with alcohol use disorder are prone to a variety of serum electrolyte disorders including hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphatemia. The etiology of hypophosphatemia in patients with alcohol use disorder is multifactorial. Malnutrition, poor dietary intake, diarrhea, vomiting, and the use of phosphate-binding antacids can all contribute to hypophosphatemia related to alcohol use disorder.[80] In addition, serum phosphate concentrations may decrease after hospitalization in patients with alcohol use disorder with the institution of dextrose-containing IV fluids as a result of an intracellular shift of phosphate.[78,80] Hyperventilation associated with the alcohol withdrawal syndrome can also contribute to the development of hypophosphatemia.[78] Patients with alcohol use disorder are particularly susceptible to the complications of hypophosphatemia such as rhabdomyolysis, which is often seen during withdrawal or refeeding.[78] Thus, serum phosphate concentrations should be routinely monitored in this patient population.

Clinical Presentation: Hypophosphatemia

CLINICAL PRESENTATION: Hypophosphatemia

General

- Major conditions associated with symptomatic hypophosphatemia are chronic alcohol use disorder, nutrition support without adequate phosphate supplementation, and the chronic ingestion of antacids. Severe hypophosphatemia can also be seen during treatment of DKA and with prolonged hyperventilation.

Symptoms

- Except for the effects on mineral metabolism, the symptoms of hypophosphatemia are caused by two consequences (reduction of red cell 2,3-DPG and reduction of intracellular ATP concentrations), and can impact virtually all organ systems. The symptoms are predominantly neurological and can include irritability, apprehension, weakness, numbness, paresthesia, and confusion. Severe acute development of hypophosphatemia can result in seizures or coma.

Signs

- The initial response of bone to hypophosphatemia contributes to hypercalcemia and hypercalciuria. Prolonged hypophosphatemia can also result in rickets and osteomalacia.
- Neurologic: Severe hypophosphatemia can lead to a metabolic encephalopathy.
- Cardiopulmonary: Impaired myocardial contractility, respiratory failure secondary to ATP depletion, heart failure, new onset or worsening of an existing condition.
- Musculoskeletal: Proximal myopathy, dysphagia, and ileus have been reported. Acute hypophosphatemia superimposed on preexisting severe phosphate depletion can lead to rhabdomyolysis.
- Hematologic: Alterations in the hematopoietic system can also occur, resulting in hemolysis, reduction in phagocytotic and granulocyte chemotactic ability, as well as defective clot retraction and thrombocytopenia.

Laboratory Tests

- Serum phosphate concentrations less than 2.7 mg/dL (0.87 mmol/L) are indicative of hypophosphatemia; however, symptomatic hypophosphatemia typically is not evident until serum phosphate less than 1.5 mg/dL (0.48 mmol/L).

The clinical manifestations of severe hypophosphatemia are diverse and many organ systems can be affected. It is likely that two primary biochemical abnormalities are responsible for most of the clinical manifestations of severe hypophosphatemia.[74] First, intracellular energy stores may be decreased secondary to depletion of intracellular ATP. This can result in disruptions in cellular function. Second, reduced red blood cell 2,3-DPG concentrations are associated with a shift to the left of the oxyhemoglobin saturation curve. This shift is associated with a decrease in the release of oxygen to peripheral tissues (secondary to increased oxygen affinity for hemoglobin) and may result in tissue hypoxia.[74] These metabolic disorders can be seen in a wide variety of organ systems.

Neurologic manifestations of severe hypophosphatemia can result in a metabolic encephalopathy syndrome characterized by irritability, apprehension, weakness, numbness, paresthesia, dysarthria, confusion, obtundation, seizures, and coma has been described in patients with severe hypophosphatemia.[75,78] Neuropsychiatric disturbances include apathy, delirium, hallucinations, and paranoia. Peripheral neuropathy and symptoms resembling Guillain–Barré syndrome have also been reported.[78]

Severe hypophosphatemia can result in significant dysfunction of skeletal muscle ranging from myalgia, bone pain, and weakness, with chronic hypophosphatemia, to potentially fatal rhabdomyolysis with severe acute hypophosphatemia.[75] Laboratory evaluations can help distinguish between chronic and acute on chronic hypophosphatemia. Elevated alkaline phosphatase, normal creatine phosphokinase, and normal to low phosphate and calcium are present in cases of chronic hypophosphatemia. In contrast, hyperkalemia, hyperuricemia, elevated blood urea nitrogen and creatinine, hypercalcemia, and myoglobinuria are often present in cases in which rhabdomyolysis complicates the acute or chronic hypophosphatemia.[68] Hypophosphatemia can result in acute respiratory failure secondary to respiratory muscle weakness and diaphragmatic contractile dysfunction. Thus, frequent assessment of serum phosphate concentration is indicated in patients at risk for respiratory failure.[74] Likewise, adequate treatment of hypophosphatemia in respiratory failure can aid in successful weaning from the ventilator.[74] Dysphagia and ileus have also been attributed to hypophosphatemia.[74]

Myocardial dysfunction may be impaired in the setting of hypophosphatemia and can result in congestive cardiomyopathy. This has been observed in patients with alcohol use disorder, and postoperative and critically ill patients. Depletion of cardiac ATP stores may be the cause of this syndrome.[81] Arrhythmias have also been reported in patients with hypophosphatemia. Because hypophosphatemia is a potentially reversible cause of heart failure, it should be considered in patients who experience an acute deterioration in ventricular function.

Hematologic manifestations of hypophosphatemia include decreased concentrations of 2,3-DPG, decreased red blood cell ATP, and membrane rigidity.[81] When red blood cell ATP decreases, cells become spherocytic and rigid, and are trapped and destroyed in the spleen.[81] Therefore, hemolysis can be a manifestation of severe hypophosphatemia. Reduction in ATP content of white blood cells can result in mobility, chemotaxis, phagocytosis, and bactericidal dysfunction.[78,81] These changes can contribute to an increased risk of infection in patients with hypophosphatemia.

Finally, prolonged hypophosphatemia may result in osteopenia and osteomalacia because of enhanced osteoclastic resorption of bone and limited crystallization constituents (phosphate), respectively.[80]

Treatment

Desired Outcomes

The goals of therapy are the reversal of signs and symptoms of hypophosphatemia, normalization of serum phosphate concentrations, and management of underlying conditions. Awareness of the clinical situations in which hypophosphatemia is anticipated (eg, alcohol use disorder, DKA, initiation of nutrition support in severely malnourished) is of vital importance in preventing and managing hypophosphatemia.

Pharmacologic Therapy

Pharmacologic treatment for hypophosphatemia will typically involve phosphorus salt supplementation. The acuity and other electrolyte conditions dictate the salt, formulation, and route of administration (Table 69-5).

TABLE 69-5

Oral Phosphorus Replacement Therapy with Phosphate, Potassium, and Sodium Content Per Packet or Tablet

Product	Phosphate Content	Potassium Content	Sodium Content
Packet			
Phos-NaK®	250 mg (8 mmol)	280 mg (7.1 mEq)	160 mg (6.9 mEq)
Tablet			
Av-Phos 250 Neutral®	250 mg (8 mmol)	45 mg (1.1 mEq)	298 mg (13 mEq)
K-Phos Neutral®	250 mg (8 mmol)	45 mg (1.1 mEq)	298 mg (13 mEq)
K-Phos No. 2®	250 mg (8 mmol)	88 mg (2.3 mEq)	134 mg (5.8 mEq)
Phospha 250 Neutral®	250 mg (8 mmol)	45 mg (1.1 mEq)	298 mg (13 mEq)
Phospho-Trin 250 Neutral®	250 mg (8 mmol)	45 mg (1.1 mEq)	298 mg (13 mEq)
Virt-Phos 250 Neutral®	250 mg (8 mmol)	45 mg (1.1 mEq)	298 mg (13 mEq)

Phosphorus 31 mg = 1 mmol; potassium 39 mg = 1 mEq = 1 mmol; sodium 23 mg = 1 mEq = 1 mmol.

Mild-to-Moderate Hypophosphatemia

Mild-to-moderate (1.5-2.7 mg/dL [0.48-0.87 mmol/L]) or asymptomatic hypophosphatemia can generally be treated by the administration of oral phosphate salts. Fixed-dose and weight-based phosphate supplementation may be used.[1] Oral phosphate salts in divided doses of 1 to 2 g (32-64 mmol) daily can be provided for mild-to-moderate hypophosphatemia (see Table 69-5). Phosphate concentrations should be monitored daily, with the goal of correcting the reduced phosphate concentration in approximately 7 to 10 days. The primary dose-limiting adverse medication reaction associated with oral phosphate replacement is the development of osmotic diarrhea. For patients who are unable to receive oral supplements, IV phosphorus supplementation may be required. A graduated dosing scheme for IV treatment of hypophosphatemia may be used in patients with normal kidney function.[1] For mild hypophosphatemia (2.3-2.7 mg/dL [0.74-0.87 mmol/L]), an IV phosphate dose of 0.08-0.16 mmol/kg is recommended.[1] In moderate hypophosphatemia (1.5-2.2 mg/dL [0.48-0.71 mmol/L]), an IV phosphate dose of 0.16-0.32 mmol/kg is recommended.[1] Patients with mild-to-moderate hypophosphatemia and impaired kidney function should receive reduced doses, typically ≤ 50% of the initial empiric dose, with careful monitoring of serum phosphate concentration because they are predisposed to phosphate retention.[1] In the setting of obesity (weight >130% IBW or BMI ≥ 30 kg/m^2), an adjusted body weight may be used to calculate phosphorus requirements to avoid overdosing. The maximum rate of IV phosphorus infusion is 7.5 mmol/hr.[1] Potassium and sodium are the available salts for IV phosphorus administration. For patients with concomitant hypokalemia, potassium phosphate can be used (1 mmol potassium phosphate = 1.47 mEq K).[1] Patients with hypophosphatemia and normal or elevated serum potassium concentrations should be treated with sodium phosphate (1 mmol sodium phosphate = 1.33 mEq Na).[1] In addition to phosphate supplementation for hypophosphatemia, dipyridamole can decrease renal phosphate leaking and increase serum phosphate. Doses of 75 mg four times daily have resulted in increases in serum 1,25-dihydroxyvitamin D$_3$ and decreases in serum calcium and urolithiasis events.[82]

Severe Hypophosphatemia

⑧ Patients with severe (less than 1.5 mg/dL [0.5 mmol/L]) or symptomatic hypophosphatemia should be treated with parenteral phosphate replacement. Thus, dosage and infusion recommendations, as well as response to parenteral phosphate replacement, are highly variable.[83] For severe symptomatic hypophosphatemia (<1.5 mg/dL [0.48 mmol/L]), an IV phosphate dose of 0.32 to 0.64 mmol/kg is recommended for patients with normal kidney function.[1] In critically ill trauma patients, doses up to 1 mmol/kg have been used.[84] IV phosphate therapy produces the desired increase in serum phosphate at 24 hours in 20% to 80% of patients. Response is dependent on the degree of phosphate depletion and replacement dose administered.[80] The initial success is often followed in 48 to 72 hours by recurrent hypophosphatemia, necessitating close monitoring of serum phosphate and repeat administration of phosphate products as warranted.

Adverse Medication Reactions of Parenteral Phosphate

Parenteral phosphate supplementation is associated with risks of hyperphosphatemia, metastatic soft tissue deposition of calcium-phosphate product, hypomagnesemia, hypocalcemia, hyperkalemia or hypernatremia (dependent on which IV phosphate formulation is administered), and thrombophlebitis from potassium phosphate. Inappropriate administration of large doses of parenteral phosphate over relatively short time periods has resulted in symptomatic hypocalcemia and soft-tissue calcification.[61] The rate of infusion and choice of initial dosage should therefore be based on severity of hypophosphatemia, presence of symptoms, and coexistent medical conditions. Patients should be closely monitored with frequent serum phosphate determinations for 48 to 72 hours after starting IV therapy. Opinions are mixed regarding the optimal time to reevaluate serum phosphorus after supplementation. Monitoring serum phosphorus 12 to 24 hours after supplementation or daily may be sufficient.[1] However, for patients with severe hypophosphatemia, more frequent monitoring may be warranted.[1] It can be necessary to continue administration of IV phosphate for several days in some patients, although other patients may be able to tolerate an oral maintenance regimen. Monitoring should also include assessment of serum potassium, calcium, and magnesium concentrations. Hypomagnesemia secondary to intracellular shifts occurs frequently (27%-80%) in patients with severe hypophosphatemia.[70] Therapy with parenteral phosphate should be undertaken with great caution and at reduced dosage for patients with hypercalcemia or impaired kidney function.[78]

CONCLUSION

Initial treatment strategy should be based on acuity of onset and severity of symptoms. Because the etiologies of calcium and phosphate disorders are diverse, it is important to integrate the known or anticipated consequences of concomitant diseases into the treatment strategy. The patient's medication history should be comprehensively assessed to determine whether the electrolyte abnormality may be medication induced. After resolution or treatment of the acute calcium or phosphate disorder, the medication regimen should be evaluated periodically. This proactive interventional approach will facilitate the management of mild disorders in the community and can reduce the need for hospitalization.

ABBREVIATIONS

2,3-DPG	2,3-diphosphoglycerate

SELF-ASSESSMENT QUESTIONS

1. A malignancy associated with hypercalcemia from PTH-related protein is:

   A. Breast

   B. Prostate

   C. Leukemia

   D. Cervical

2. An adult female was found at home obtunded. Upon arriving to the hospital, she was diagnosed with rhabdomyolysis and acute kidney injury. Laboratory data include serum calcium 8.3 mg/dL (2.08 mmol/L), serum albumin of 1.2 g/dL (12 g/L), and serum phosphorus 2.3 mg/dL (0.74 mmol/L). Which of the following electrolyte disorders is *most likely* from this patient's rhabdomyolysis-induced acute kidney injury?

   A. Hypocalcemia

   B. Hypercalcemia

C. Hyperphosphatemia

D. Hypophosphatemia

3. CP, an adult female with stage 4 renal cell carcinoma, presents to the emergency department with profound weakness, abdominal pain with nausea and vomiting, and dehydration. Laboratory data include: sodium 135 mEq/L (mmol/L), potassium 4.5 mEq/L (mmol/L), chloride 101 mEq/L (mmol/L), bicarbonate 24 mEq/L (mmol/L), serum creatinine 1.2 mg/dL (106 µmol/L), BUN 40 mg/dL (14.3 mmol/L), and serum calcium 14.2 mg/dL (3.55 mmol/L). What is the *most likely* cause of CP's hypercalcemia?

   A. Primary hyperparathyroidism

   B. Secondary hyperparathyroidism associated with kidney disease

   C. Bone metastases

   D. Excessive endogenous Vitamin D production

4. Which of the following is the *most appropriate initial* therapy for CP?

   A. Hemodialysis with a low calcium bath

   B. High-dose IV loop diuretic

   C. Saline hydration

   D. Intravenous bisphosphonate

5. An adult female with asymptomatic hypercalcemia secondary to metastatic lung cancer presents with a serum calcium of 12.2 mg/dL (3.05 mmol/L). Her serum creatinine is 0.9 mg/dL (80 µmol/L) and estimated glomerular filtration rate >60 mL/min/1.73 m^2. The decision is made to initiate therapy with an agent that inhibits bone resorption. Based on the efficacy and toxicity profile of the following agents, which would be the *most appropriate* to initiate in this patient?

   A. Prednisone

   B. Pamidronate

   C. Calcitonin

   D. Denosumab

6. Which treatment is *most appropriate* to reduce stone number and diameter in an adult patient with primary hyperparathyroidism?

   A. Cinacalcet

   B. Calcium-restricted diet

   C. Lithotripsy

   D. Etelcalcitide

7. An adult female with chronic kidney disease stage 3b (estimated GFR 40 mL/min/1.73 m^2) is scheduled to have a colonoscopy. Her oral medications include: ramipril 10 mg once daily, furosemide 80 mg twice daily, and metoprolol succinate 50 mg once daily. Prior to her colonoscopy, she is advised to use a sodium phosphate bowel preparation. All but which of the following put her at increased risk for phosphate nephropathy or acute kidney injury?

   A. Chronic kidney disease

B. Ramipril

C. Metoprolol succinate

D. Furosemide

8. A critically ill adult male is asymptomatic with a serum calcium of 8.1 mg/dL (2.03 mmol/L). Ionized calcium and albumin have not been evaluated. What is the *most appropriate* recommendation regarding this patient's serum calcium concentration?

A. Check an ionized calcium concentration

B. Administer calcium chloride 1 g IV over 10 minutes

C. Administer calcium gluconate 2 g IV over 2 hours

D. Administer calcium gluconate 3 g IV over 3 hours

9. An adult female presents with asymptomatic hypocalcemia secondary to vitamin D deficiency. She has no kidney or hepatic impairment. Which of the following is the *most appropriate* therapy to initiate at this time?

A. Calcitriol

B. Doxercalciferol

C. Ergocalciferol

D. Paricalcitol

10. What mechanism may cause drug-induced hypocalcemia from bisphosphonates?

A. Blocked bone resorption

B. Increased sensitivity to CaSr

C. Decreased PTH sensitivity

D. Induction of hypomagnesemia

11. An adult female with stage 4 chronic kidney disease is treated for iron deficiency anemia with ferric carboxymaltose 750 mg IV. She reports significant myalgias and weakness one week after the infusion. Which of the following electrolyte disorders is the *most likely* the cause of her symptoms?

A. Hypercalcemia

B. Hypocalcemia

C. Hyperphosphatemia

D. Hypophosphatemia

12. An adult female with chronic disease-related malnutrition who underwent surgery for esophageal cancer is initiated on enteral nutrition. Laboratory data prior to enteral nutrition included: serum phosphorus 4 mg/dL (1.29 mmol/L) and serum potassium 4.1 mEq/L (mmol/L). Laboratory data 24 hours after initiation of enteral nutrition included: serum phosphorus 0.8 mg/dL (0.26 mmol/L) and serum potassium 2.6 mEq/L (mmol/L). Which of the following *best* describes the pathogenesis of her hypophosphatemia?

A. Decreased gastrointestinal absorption

B. Decreased tubular reabsorption

C. Increased internal redistribution

D. Increased renal excretion

13. An adult hospitalized male (93 kg, 6 ft 1 in.' [185 cm]) has the following current laboratory data: magnesium 2.1 mEq/L (0.86 mmol/L), phosphorus 1.2 mg/dL (0.39 mmol/L), sodium 136 mEq/L (mmol/L), potassium 5.9 mEq/L (mmol/L), blood urea nitrogen 10 mg/dL (3.6 mmol/L), and serum creatinine 0.9 mg/dL (80 µmol/L). What is the *most appropriate* electrolyte replacement at this time?

A. K-Phos No. 2® 250 mg tablet orally every 6 hours

B. Phos-NaK® 250 mg packet orally every 6 hours

C. Sodium phosphate 45 mmol IV once

D. Potassium phosphate 45 mmol IV once

14. An older male who resides in a nursing home develops hypophosphatemia (serum phosphorus 1.7 mg/dL [0.55 mmol/L]) secondary to limited oral intake associated with advanced dementia. His other laboratory data include: serum potassium 3.4 mEq/L (mmol/L) and total corrected calcium 8.5 mg/dL (2.13 mmol/L). Which of the following is the *best* therapy to initiate in this patient?

A. Neutra-Phos-K®

B. K-Phos Neutral®

C. Neutra-Phos®

D. Potassium phosphate IV

15. Hemolysis related to hypophosphatemia is *most likely* caused by which of the following?

A. Altered cardiac conduction

B. Depletion of ATP stores

C. Myocardial cell apoptosis

D. Vitamin D deficiency

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Rationale: Many tumors secrete PTH-related protein, which binds the PTH receptors on bone and in kidney tissues, inducing bone resorption and increasing tubular reabsorption of calcium. Breast cancer is associated with hypercalcemia from PTH-related protein. See the "Pathophysiology" (Hypercalcemia) section.

2. **B.** Rationale: Rhabdomyolysis can induce hypercalcemia due to mobilization of calcium from calcium phosphate deposits in the injured muscles. Severe, rapidly developing hypercalcemia can result in obtundation. See the "Pathophysiology" (Hypercalcemia) section.

3. **C.** Rationale: Cancers that metastasize to bone can cause hypercalcemia. See the "Pathophysiology" (Hypercalcemia) section.

4. **C.** Rationale: First-line therapy for patients with relatively intact kidney function is volume expansion with normal saline to induce calciuresis. See the "Pharmacologic Therapy" (Hypercalcemia) section.

5. **B.** Rationale: Bisphosphonates are first-line for treating hypercalcemia of malignancy. Calcitonin is associated with tachyphylaxis, and prednisone

has a slow onset and extensive adverse medication reaction profile. Denosumab is a good option for patients with impaired kidney function. See the “Pharmacologic Therapy” (Hypercalcemia) section.

6. **A.** Rationale: Cinacalcet reduces stone number and diameter. Etelcalcitide is also a calcimimetic; however, it is only approved to treat secondary hyperparathyroidism in patients undergoing hemodialysis. See the “Pharmacologic Therapy” (Hypercalcemia) section.

7. **C.** Rationale: Metoprolol succinate does not affect renal hemodynamics whereas ramipril causes dilation of the efferent arteriole and furosemide can induce volume depletion. Chronic kidney disease will impair her ability to excrete phosphorus. See the “Pathophysiology” (Hyperphosphatemia) section.

8. **A.** Rationale: The serum calcium is not low enough to warrant treating without evaluating the ionized calcium first. Ionized calcium is the gold standard for calcium monitoring in critically ill patients. See the “Disorders of Calcium Homeostasis” and “Acute Treatment” (Hypocalcemia) sections.

9. **C.** Rationale: Ergocalciferol is an appropriate therapy for an adult patient with asymptomatic hypocalcemia secondary to vitamin D deficiency and no kidney or hepatic impairment. See the “Chronic Treatment” in Hypocalcemia section.

10. **A.** Rationale: Bisphosphonates may cause hypocalcemia by the mechanism of blocked bone resorption. While the other answer choices are mechanisms that may cause hypocalcemia, they are associated with other medications. See the “Medication-induced Hypocalcemia” section.

11. **D.** Rationale: Based on her history of ferric carboxymaltose administration one week ago, hypophosphatemia is the most likely cause of her symptoms. See the “Pathophysiology” (Hypophosphatemia) section.

12. **C.** Rationale: Hypophosphatemia in the setting of refeeding syndrome occurs as a result of internal redistribution or intracellular shifts of phosphate. See the “Pathophysiology” (Hypophosphatemia) section.

13. **C.** Rationale: In the setting of severe hypophosphatemia and normal kidney function, parenteral phosphate replacement with 0.32 to 0.64 mmol/kg is recommended (30-60 mmol based on the patient’s weight of 93 kg). Oral replacement is inappropriate because of the severity and the patient should not receive potassium phosphate in the setting of hyperkalemia. See the “Severe Hypophosphatemia” (Treatment) section.

14. **A.** Rationale: Since the patient has asymptomatic hypokalemia and hypophosphatemia, treatment with an oral agent including potassium is the best choice. See the “Mild-to-Moderate Hypophosphatemia” (Treatment) section.

15. **B.** Rationale: When red blood cell ATP decreases, cells become spherocytic and rigid, and are trapped and destroyed in the spleen. See the “Pathophysiology” (Hypophosphatemia) section.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 70: Disorders of Potassium and Magnesium Homeostasis

Rachel W. Flurie

KEY CONCEPTS

KEY CONCEPTS

① Potassium regulates many biochemical processes in the body and is a key cation for electrical action potentials across cellular membranes.

② The kidney is the primary route of potassium elimination.

③ In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia before the hypokalemia.

④ Potassium chloride is the preferred potassium supplement for the most common causes of hypokalemia.

⑤ Hyperkalemia is a common occurrence in patients with acute kidney injury or chronic kidney disease.

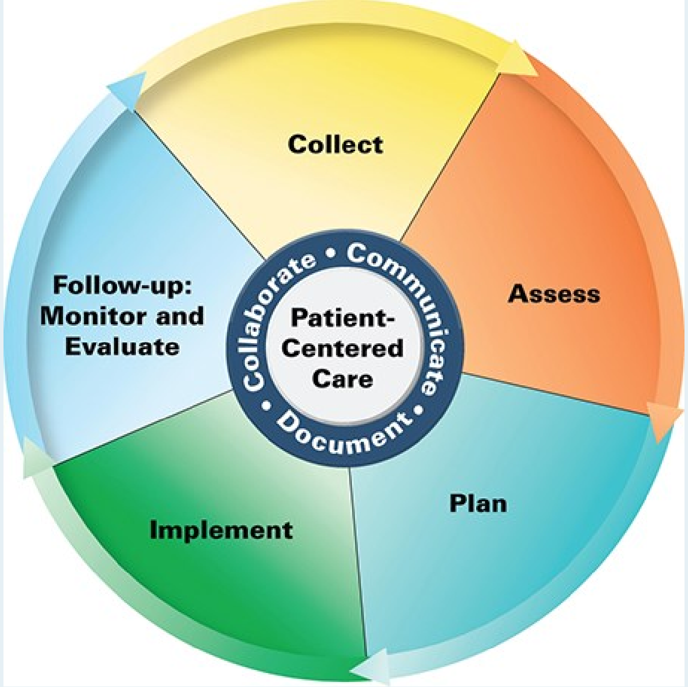
⑥ Hypomagnesemia is commonly caused by excessive gastrointestinal or renal magnesium wasting.

⑦ Hypermagnesemia is predominantly observed in patients with acute or chronic kidney disease.

⑧ Severe hypermagnesemia may affect the neuromuscular and cardiovascular systems.

PATIENT CARE PROCESS

Patient Care Process* for the Management of Potassium and Magnesium Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex)
- Patient history (past medical, family, social–dietary habits)
- Current medications including over-the-counter medications, herbals, dietary supplements
- Subjective data
    - Musculoskeletal and neuromuscular review of systems
    - Intake (food and fluid) and output (urine and stool)
- Objective data
    - Blood pressure, heart rate, height, weight
    - Labs (eg, basic metabolic panel, calcium, magnesium, phosphorus)
    - Other diagnostic tests when indicated (eg, electrocardiogram [ECG], urinalysis, urine electrolytes)

Assess

- Presence of symptoms of an electrolyte disorder
- Presence of ECG changes (see Fig. 70-1)
- Severity of electrolyte disorder (eg, change from baseline value, timing of development of electrolyte disorder)
- Kidney function (eg, estimated glomerular filtration rate [GFR], creatinine clearance [CrCl], presence of chronic kidney disease [CKD])
- Current medications that may contribute to electrolyte disorder (see Tables 70-1, 70-6, and 70-8)
- Current diet that may contribute to electrolyte disorder (see Tables 70-2 and 70-9)

Plan*

- Identification of the most likely cause of the electrolyte disorder and discontinuation of offending medication or substance (if applicable)
- Dietary modifications (see Tables 70-2 and 70-9)
- Medication therapy regimen including specific medication, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Tables 70-4, 70-5, and 70-7)
- Monitoring parameters including efficacy (eg, potassium, magnesium, serum creatinine [SCr]), safety (medication-specific adverse medication reactions), and need for repeat or additional medication therapy
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, medication therapy)
- Referrals to other providers when appropriate (eg, physician, dietitian)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Resolution of electrolyte disorder and prevention of further episodes
- Presence of adverse medication reactions
- Development/progression of kidney impairment
- Patient adherence to treatment plan using multiple sources of information

[*] *Collaborate with patient, caregivers, and other health professionals*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Hyperkalemia in Primary Care Practice” by the National Kidney Foundation. (https://www.kidney.org/content/hyperkalemia-primary-care-practice) This ~11-minute video provides a brief overview of the risks associated with hyperkalemia, the various causes of hyperkalemia, and prevention and treatment strategies. The video is useful to enhance student understanding of the COLLECT, ASSESS, and PLAN steps in the patient care process.

INTRODUCTION

Potassium and magnesium are electrolytes that are responsible for numerous metabolic activities. Disorders of these electrolytes are frequently seen in both the acute care and community ambulatory care settings. Therefore, clinicians need a firm understanding of the etiology, pathophysiology, symptoms, pharmacotherapy, and monitoring of these disorders. This chapter describes the homeostatic mechanisms that are responsible for the maintenance of normal potassium and magnesium serum concentrations. The clinical disorders responsible for the development of hyperkalemia, hypermagnesemia, hypokalemia, and hypomagnesemia are also reviewed.

POTASSIUM

Potassium is the most abundant cation in the body, with estimated total-body stores of 3,000 to 4,000 mEq (mmol).[1] Ninety-eight percent of this amount is contained within the intracellular compartment, and the remaining 2% is distributed within the extracellular compartment. The sodium-potassium adenosine triphosphatase (Na^+-K^+-ATPase) pump located in the cell membrane is responsible for the compartmentalization of potassium. This pump is an active transport system that maintains increased intracellular stores of potassium by transporting sodium out of the cell and potassium into the cell at a ratio of 3:2. Consequently, the pump maintains a higher concentration of potassium inside the cell.

The normal serum concentration range for potassium is 3.5 to 5 mEq/L (mmol/L), whereas the intracellular potassium concentration is approximately 150 mEq/L (mmol/L).[2] Approximately 75% of the intracellular potassium is located in skeletal muscle; the remaining 25% is located in the liver and red blood cells. Extracellular potassium is distributed throughout the serum and interstitial space. Potassium is dynamic in that it is constantly moving between the intracellular and extracellular compartments according to the body’s needs. Thus, the serum potassium concentration alone does not accurately reflect the total-body potassium content.

① Potassium has many physiologic functions within cells, including protein and glycogen synthesis and cellular metabolism and growth. It is also a determinant of the electrical action potential across the cell membrane.[1] The ratio of the intracellular-to-extracellular potassium concentration is the major determinant of the resting membrane potential across the cell membrane. Serum potassium concentrations outside the normal range can have disastrous effects on neuromuscular activity, in particular cardiac conduction. Hypo- and hyperkalemia are both associated with potentially fatal cardiac arrhythmias, along with other neuromuscular disturbances. Finally, potassium is integral to maintaining blood pressure, prevention of stroke, and potentially other cardiovascular diseases.[3] Both the National High Blood Pressure Education Program and the Institute of Medicine recommend potassium supplementation as a strategy for preventing and treating hypertension.[4,5]

Control of Potassium Homeostasis

Potassium homeostasis, the maintenance of serum potassium within the normal range, is affected by dietary intake, gastrointestinal (GI) and urinary excretion, hepatic and muscular sequestration, hormones, acid-base balance, body fluid tonicity, central and peripheral circadian clocks, and a highly integrated feedback mechanism.[6,7] Together, these mechanisms usually maintain total-body potassium content within a narrow window without appreciable changes in the serum potassium concentration.[6] Deviations in serum potassium concentrations outside of the normal range are a result of nonhomeostatic processes that are not sensitive to changes in potassium balance.[6] The recommended adequate intake of dietary potassium in the United States is 2,600 mg/day for adult females and 3,400 mg/day for adult males.[8] Potassium is considered to be a nutrient of concern, because of its beneficial effects on blood pressure, reduction in the risk of kidney stones, and decrease of bone loss.[9] Potassium is abundant in fruits, vegetables, meats, whole grains, and milk products. Most dietary potassium is absorbed, with only 10 to 20 mEq/day (mmol/day) eliminated in feces. The amount eliminated in the feces increases, however, in patients with diarrhea and in those with CKD.[7]

② The kidney is the primary route of potassium elimination. Potassium is freely filtered, but almost all of it is reabsorbed passively in the proximal tubule and the thick ascending limb of the loop of Henle.[9] Although the amount of potassium filtered by the glomerulus approaches 700 mEq (mmol) per day, only approximately 10% to 20% is actually excreted in the urine.[9] Potassium excretion is regulated by its secretion into the distal tubule and collecting duct. Variations in potassium excretion are based on dietary intake, serum potassium concentration, and aldosterone activity. For example, more potassium is renally excreted in conditions that result in high aldosterone activity (eg, dehydration) when the body is attempting to conserve sodium or when there is an increase in dietary potassium intake. In addition, enteric solute sensors increase kaliuresis in response to high dietary potassium intake.[1]

Hormones such as insulin, catecholamines, and aldosterone dramatically affect potassium homeostasis. Aldosterone controls renal potassium excretion, which can take several hours to adjust serum potassium concentrations. Rapid buffering of serum potassium concentrations occurs through potassium cellular redistribution, of which insulin and catecholamines play a large role. Insulin is the most important hormonal mediator of potassium balance because it stimulates the cellular Na^+-K^+-ATPase pump to increase transport of potassium into liver, muscle, and adipose tissue.[6] There is a complex negative feedback loop in which insulin secretion tightly regulates serum potassium concentrations: an increase of only a few tenths of a milliequivalent (mmol) of potassium stimulates pancreatic insulin secretion in an attempt to prevent hyperkalemia from developing.[1] If hyperkalemia does occur, glucagon is released from the liver to protect against insulin-induced hypoglycemia. Conversely, hypokalemia inhibits insulin secretion, a finding that explains why some patients receiving diuretics develop hyperglycemia.

An elevation in circulating catecholamines such as epinephrine usually results in the intracellular movement of potassium by two mechanisms.[9] Stimulation of the *β*-receptor, which directly activates the Na^+-K^+-ATPase pump and glycogenolysis, which raises blood glucose concentrations, thereby increasing insulin secretion. This dual mechanism is often used therapeutically in patients with hyperkalemia to normalize serum potassium concentrations.

Aldosterone, a mineralocorticoid that is secreted from the adrenal glands in response to high serum potassium concentrations, promotes urinary potassium excretion. Aldosterone acts on the distal tubule and collecting duct to promote the reabsorption of sodium and water in exchange for potassium. It also increases potassium permeability and transport across the luminal membrane of the nephron by stimulating the cellular Na^+-K^+-ATPase pump activity.[7] In patients with impaired kidney function aldosterone increases potassium excretion in the distal colon.[10]

Changes in acid–base status can dramatically affect the serum potassium concentration. For example, the infusion of metabolic inorganic acids, such as hydrochloric acid, results in an increase in serum potassium. The body compensates for excessive hydrogen ions by moving them from the serum into the cell in exchange for intracellular potassium, to maintain electroneutrality. The processes by which this occurs are highly complex and involve cellular H^+-K^+-ATPase pumps and both $\mathrm{Na}^+-\mathrm{HCO}_3^-$Na+−HCO3− and $\mathrm{K}^+-\mathrm{HCO}_3^-$K+−HCO3− cotransporters.[11] The efflux of potassium into the serum can result in hyperkalemia. A commonly quoted approximation of the pH effect is that for every 0.1 unit decrease in pH, serum potassium concentration increases by 0.6 to 0.8 mEq/L (mmol/L) (with a wide range of 0.2-1.7).[12] This is often referred to as *false hyperkalemia* because there is not a true excess of total-body potassium. Metabolic acidosis associated with lactic acidosis and ketoacidosis typically does not lead to clinically significant hyperkalemia, because both cations and anions enter the cell, thus maintaining electroneutrality.[1] Respiratory acidosis also does not significantly affect the serum potassium concentration.

Conversely, metabolic alkalosis has been associated with hypokalemia. As a result of a net loss of hydrogen ion from the serum, intracellular hydrogen ions enter the serum to increase the acidity of the blood. To maintain electroneutrality, extracellular potassium ions are shifted intracellularly. This creates a relative deficiency of potassium in the serum. Serum potassium decreases approximately 0.6 mEq/L (mmol/L) for each 0.1 unit increase in blood pH. This is frequently termed *false hypokalemia* because there is not a true deficiency in total-body potassium.

Finally, hyperosmolality can result in enhanced movement of potassium from the cell into the extracellular fluid. Water movement favors potassium efflux through solvent drag. As cells shrink, intracellular potassium concentrations increase, further promoting potassium efflux.[7] This is seen in conditions such as diabetic ketoacidosis. Conversely, hypoosmolality does not seem to affect potassium distribution.

HYPOKALEMIA

Epidemiology

Hypokalemia (defined as a serum potassium concentration less than 3.5 mEq/L [mmol/L]) is a commonly encountered electrolyte abnormality in clinical practice. Hypokalemia is often categorized as mild (serum potassium 3.1-3.4 mEq/L [mmol/L]), moderate (serum potassium 2.5-3 mEq/L [mmol/L]), or severe (less than 2.5 mEq/L [mmol/L]).[13] When hypokalemia is detected, the diagnostic workup should evaluate the patient's comorbid disease states and concomitant medications. Hypokalemia is virtually nonexistent in healthy adults. This is due in part to the potassium content in the typical Western diet as well as the body's effective potassium-sparing mechanisms, which tightly regulate the serum potassium concentration. However, as many as 20% of hospitalized patients and up to 40% of patients taking thiazide diuretics will develop hypokalemia.[14]

While transient hypokalemia may be thought of as merely a laboratory abnormality, there are serious potential consequences associated with persistent hypokalemia. Hypokalemia increases mortality in patients with heart failure, CKD, or diabetes mellitus, populations typically thought to be more sensitive to the effects of hyperkalemia.[15] Low dietary potassium intake is associated with worsening hypertension and higher risk of stroke.[3]

Etiology and Pathophysiology

Hypokalemia results when there is a total-body potassium deficit, or when serum potassium is shifted into the intracellular compartment. Total-body deficits occur in the setting of poor dietary intake of potassium, or when there are excessive renal and GI losses of potassium. Maintaining a consistent dietary intake of potassium is important because the body has no effective method for storing potassium. At steady state, potassium excretion matches potassium intake; approximately 90% of ingested potassium is renally excreted, whereas 10% is excreted in feces.[9] This underscores the importance of eating a well-balanced diet. Older adults with chronic diseases and those undergoing surgery are at increased risk for developing hypokalemia because of insufficient intake or losses resulting from surgery.

Many medications can cause hypokalemia by a variety of mechanisms including intracellular potassium shifting and increased renal or stool losses (Table 70-1). The most common cause of medication-induced hypokalemia is loop and thiazide diuretic administration as these agents inhibit sodium reabsorption in the kidney, which results in increased sodium delivery to the distal tubule. Consequently, hypokalemia develops because the distal tubule selectively reabsorbs sodium and excretes potassium. Second, because diuretics result in vascular volume contraction, aldosterone is secreted that further promotes the renal excretion of potassium. If concomitant potassium supplements are not provided to patients receiving loop and thiazide diuretics, mild-to-moderate hypokalemia is inevitable.

TABLE 70-1

Mechanism of Medication-Induced Hypokalemia

Transcellular Shift	Enhanced Renal Excretion	Enhanced Fecal Elimination
β_2-Receptor agonists Epinephrine Albuterol Terbutaline Fomoterol Salmeterol Isoproterenol Ephedrine Pseudoephedrine Theophylline Levothyroxine Decongestants Caffeine Insulin overdose Verapamil overdose Barium overdose	Diuretics Acetazolamide Thiazides Indapamide Metolazone Furosemide Torsemide Bumetanide Ethacrynic acid High-dose penicillins Nafcillin Ampicillin Penicillin Mineralocorticoids Miscellaneous Aminoglycosides Amphotericin B Cisplatin	Laxatives Sodium polystyrene sulfonate Sorbitol Patiromer Sodium zirconium cyclosilicate

The second most common etiology of hypokalemia is excessive loss of potassium-rich GI fluid as a result of diarrhea and/or vomiting. The typical potassium loss in feces is approximately 10 mEq (mmol) per day.[7] In diarrheal states, this amount increases proportionally with the volume of stool output. Fecal potassium losses may be as high as 130 to 170 mEq/L (mmol/L).[16] Vomiting also accounts for substantial potassium losses, which have been estimated to be as high as 30 to 50 mEq (mmol) per liter of vomitus.[17] Metabolic alkalosis which often develops in those with severe diarrhea and vomiting as a result of loss of these bicarbonate-rich fluids causes an intracellular shift of potassium, thereby lowering the serum concentration of potassium even further. Prolonged diarrhea and vomiting tend to affect children and older adults profoundly because their kidneys are unable to effectively maintain adequate fluid status.

③ Hypomagnesemia, which is present in more than 50% of patients with clinically significant hypokalemia, contributes to the development of hypokalemia because it reduces the intracellular potassium concentration and promotes renal potassium wasting.[18] While the precise mechanism of the accelerated renal loss is unknown, many believe that the intracellular potassium concentration may decrease because hypomagnesemia impairs the function of the Na^+-K^+-ATPase pump thereby promoting potassium wasting. Alternatively, the combination of increased sodium delivery to the distal tubule, elevated aldosterone concentrations, and hypomagnesemia may cause the kidney outer medullary potassium channels to excrete more potassium.[18] What is clear is that hypokalemia and hypomagnesemia often coexist as a result of medications (diuretic administration) or disease states (diarrhea). When concomitant hypokalemia and hypomagnesemia occur, the magnesium deficiency should be corrected first; otherwise, full repletion of the potassium deficit is difficult.

Treatment

Desired Outcomes

The goals of hypokalemia management are to prevent and/or treat serious life-threatening complications, normalize the serum potassium concentration, identify and correct the underlying cause of hypokalemia, and finally prevent overcorrection of the serum potassium concentration.

General Approach to Therapy

The general approach to therapy depends on the degree and rapidity with which hypokalemia developed and the presence of signs and symptoms. Serum potassium concentrations between 3.5 and 4 mEq/L (mmol/L) are a sign of early potassium depletion. No pharmacologic therapy is recommended; however, patients should be encouraged to increase their dietary intake of potassium-rich foods. When the serum potassium concentration is between 3 and 3.4 mEq/L (mmol/L), the patient’s concomitant conditions and therapies will largely determine whether pharmacologic therapy should be initiated. Most patients will not have signs or symptoms if serum potassium concentrations remain greater than 3 mEq/L (mmol/L). The presence of signs or symptoms with mild hypokalemia warrants the initiation of potassium supplementation. Oral potassium supplementation should be initiated in patients with underlying cardiac conditions that predispose them to cardiac arrhythmias. Patients with serum potassium concentrations less than 3 mEq/L (mmol/L) should always be treated to achieve values between 4 and 4.5 mEq/L (mmol/L). In asymptomatic patients, oral therapy is the preferred route of administration. Intravenous (IV) potassium may be necessary in symptomatic patients with severe depletion, or in patients who are intolerant to oral supplementation. In patients with concomitant moderate to severe hypomagnesemia, the magnesium deficit should be corrected before potassium supplementation is started.[9,14]

CLINICAL PRESENTATION: Hypokalemia

General

- The signs and symptoms of hypokalemia are usually nonspecific and highly variable between patients.

Symptoms

- Symptoms are dependent on the degree of hypokalemia and its rapidity of onset.
- Mild hypokalemia is often asymptomatic.
- Moderate hypokalemia is associated with cramping, weakness, malaise, and myalgias.

Signs

- Cardiovascular: In severe hypokalemia, ECG changes often include ST-segment depression or flattening, T-wave inversion, and U-wave elevation. Clinical arrhythmias include heart block, atrial flutter, paroxysmal atrial tachycardia, ventricular fibrillation, and digitalis-induced arrhythmias.
- Musculoskeletal: Cramping and impaired muscle contraction.

Laboratory Tests

- Serum potassium concentration below 3.5 mEq/L (mmol/L) is diagnostic. Hypomagnesemia (serum magnesium concentration below 1.7 mg/dL [1.4 mEq/L; 0.70 mmol/L]) can also be present.

Nonpharmacologic Therapy

The best and most abundant sources of dietary potassium supplementation are fresh fruits and vegetables, fruit juices, and meats (Table 70-2). Increased dietary intake of foods with high potassium content, however, is not recommended long-term because it can add unwanted calories to the patient’s diet. Moreover, dietary potassium is almost entirely coupled with phosphate, rather than chloride, so it is not as effective in correcting potassium loss associated with hypochloremic conditions such as vomiting, nasogastric suctioning, and diuretic therapy. Salt substitutes that contain potassium chloride are another effective, inexpensive source of potassium and because they provide chloride as well and are frequently recommended.

TABLE 70-2

Foods That Are High in Potassium

High content (>250 mg)	Very high content (>500 mg)
Kidney beans, cooked	Potato, baked, flesh and skin
Lentils, cooked	Sweet potato, baked in skin
Soybeans, green, cooked	Juice, canned
Lima beans, cooked	Prunes
Soybeans, mature, cooked	Carrot

Pinto beans, cooked	Tomato
Lentils, cooked	Tomato paste
Halibut, cooked	Tomato puree
Rockfish, Pacific, cooked	Beet greens, cooked
Cod, Pacific, cooked	White beans, canned
Tuna, yellowfin, cooked	Plain yogurt, nonfat or low-fat
Rainbow trout, cooked	Clams, canned
Evaporated milk, nonfat	
Low-fat (1%) or reduced fat (2%) chocolate milk	
Skim milk (nonfat)	
Low-fat milk or buttermilk (1%)	
Orange juice, fresh	
Bananas	
Peaches, dried, uncooked	
Prunes, stewed	
Apricots, dried, uncooked	
Plantains, cooked	
Tomato sauce	
Pork loin, center rib, lean, roasted	
Spinach, cooked	

Pharmacologic Therapy

Formal guidelines for potassium supplementation were last published by the National Council on Potassium in Clinical Practice in 2000 (Table 70-3).[19] While these guidelines are not from a major medical society, they do provide a comprehensive framework for potassium administration as a prophylactic and therapeutic replacement for many patient populations. When deciding how to design the optimal regimen, one must consider: (a) the patient's normal, that is, baseline potassium concentration; (b) underlying medical conditions that can affect potassium balance; (c) concomitant medications that can affect potassium balance; (d) the patient's dietary salt intake; and (e) the patient's ability to comply with the therapeutic regimen.[19]

TABLE 70-3

General Consensus Guidelines for Potassium Replacement

Guideline	Comment
Potassium replacement therapy should accompany dietary consumption of potassium-rich foods.	Potassium-rich foods often cannot completely replace potassium associated with chloride losses (vomiting, diuretics, or nasogastric suction) because it is almost entirely coupled to phosphate. Furthermore, increasing dietary intake of these foods can lead to unwanted weight gain.
Potassium replacement is recommended for sodium-sensitive and hypertensive patients.	A high-sodium diet often results in excessive urinary potassium excretion.
Potassium replacement is recommended in patients who are subject to vomiting, diarrhea, or diuretic/laxative misuse.	These conditions promote excessive renal and GI potassium loss.
Potassium supplementation is best administered orally in divided doses over several days to achieve full repletion.	
Laboratory measurement of serum potassium is convenient, but not always accurate.	Clinicians should be aware of the factors that result in transcellular potassium shifts. Monitoring 24-hour urinary potassium excretion can be necessary in high-risk patients.
Patient adherence to potassium replacement can be increased with compliance-enhancing regimens.	Microencapsulated products have no bitter smell or aftertaste and have much better GI tolerance. Regimens should be made as simple as possible to follow.
A potassium dosage of 20 mEq/day (mmol/day) is usually sufficient to prevent hypokalemia from occurring. Doses of 40-100 mEq (mmol) are usually sufficient to treat hypokalemia.	

A general rule for potassium replacement is that for every 1 mEq/L (mmol/L) decrease of serum potassium below 3.5 mEq/L (mmol/L), there is a corresponding total-body potassium deficit of 100 to 400 mEq (mmol). Because of the wide variance in projected deficits, each patient's therapy must be individualized and adjustments made on the basis of the patient's signs, symptoms, and frequent measurements of serum potassium. In the acute care setting, the administration of 10 mEq (mmol) of IV or oral potassium should increase the serum potassium concentration by 0.1 mEq/L (mmol/L). This approximation is used as a basis for dose calculations, with frequent measurements of serum potassium to avoid overestimation. In patients receiving chronic loop or thiazide diuretic therapy, 40 to 100 mEq (mmol) of oral potassium supplementation can correct mild-to-moderate potassium deficits. Doses up to 120 mEq (mmol) can be required in more severe deficiencies. When providing oral potassium supplementation, the total daily dose should be divided into three to four doses to minimize the development of adverse medication reactions in the GI tract. Patients receiving diuretics can become chronically hypokalemic and can benefit from combination potassium-sparing diuretic therapy.

④ Whenever possible, potassium supplementation should be administered by mouth. Four salts are available for oral potassium supplementation: chloride, gluconate, phosphate, and bicarbonate. Potassium phosphate should be used when the patient is both hypokalemic and hypophosphatemic; potassium bicarbonate is most commonly used when potassium depletion occurs in the setting of metabolic acidosis. Potassium chloride, however, is the primary salt form used because it is the most effective treatment for the most common causes of potassium depletion (ie, diuretic and diarrhea-induced) as these conditions are associated with potassium and chloride losses.

Potassium chloride can be administered in either tablet or liquid formulations (Table 70-4). The liquid forms are generally less expensive; however, patient compliance can be low because of their strong, unpleasant taste. Liquid forms should be used when a rapid response to supplementation is desired. Two sustained-release solid dosage forms are currently available in the United States: a wax-matrix formulation, and a microencapsulated formulation. The microencapsulated tablet is generally preferred because it is associated with less GI irritation. IV potassium use should be limited to: (a) severe hypokalemia (serum concentration less than 2.5 mEq/L [mmol/L]); (b) patients exhibiting signs and symptoms such as ECG changes or muscle spasms; or (c) patients unable to tolerate oral therapy. IV supplementation requires more monitoring than oral therapy because it is more likely to result in hyperkalemia, phlebitis, and pain at the site of infusion.

TABLE 70-4

Differences among Oral Potassium Supplements

Supplement	Comment
Controlled-release microencapsulated tablet	Disintegrates better in GI tract; fewer GI erosions as compared to wax-matrix tablets
Encapsulated controlled-release microencapsulated particles	Fewer erosions as compared to wax-matrix tablets
Potassium chloride elixir	Inexpensive, poor taste, poor compliance, immediate effect
Potassium chloride effervescent tablets for solution	More expensive than elixir, convenient
Wax-matrix extended-release tablets	Easier to swallow; more GI erosions as compared to other therapies

The vehicle in which IV potassium is administered is important. Whenever possible, potassium should be prepared in saline-containing solutions (eg, 0.9%-0.45% sodium chloride [NaCl]). Dextrose-containing solutions stimulate insulin secretion, which can cause intracellular shifting of potassium, worsening the patient's hypokalemia, and should be avoided whenever possible. Generally, 10 to 20 mEq (mmol) of potassium is diluted in 100 mL 0.9% NaCl for IV administration. These concentrations are safe when administered through a peripheral vein over an hour. When infusion rates exceed 10 mEq/h (mmol/h), ECG monitoring should be performed to detect cardiac changes. The serum potassium concentration should be evaluated following the infusion of each 30 to 40 mEq (mmol) to guide further potassium replacement administration. Multiple doses of potassium can be repeated as needed until the serum potassium concentration normalizes. To allow adequate time for the potassium to equilibrate between the intra- and extracellular spaces, one should wait at least 30 minutes from the end of each infusion and care should be taken to avoid sampling from the same line in which the potassium was infused, as this can result in a spuriously high potassium concentration.

In patients with severe potassium depletion, replacement with as much as 300 to 400 mEq/day (mmol/day) may be needed. In this instance, it is a common practice to dilute 40 to 60 mEq (mmol) in 1,000 mL 0.45% NaCl and infuse at a rate not exceeding 40 mEq/h (mmol/h). The total 24-hour dose should not exceed 400 mEq (mmol). This should be performed in an intensive care unit (ICU) under continuous ECG monitoring. Because of the high potassium concentration and the risk for burning pain and peripheral venous sclerosis, the infusion should be through a central venous catheter into a large vein (eg, superior vena cava) but care must be taken not to place the tip of the catheter into the right atrium.[20] Directly delivering high potassium concentrations into the heart can result in cardiac arrhythmias. Given the volume required to infuse this dose of potassium, this infusion strategy might be impractical in certain clinical situations (eg, patients requiring fluid restriction). A reasonable approach is to split the potassium dose between the oral and IV routes. For example, if a symptomatic patient requires 120 mEq (mmol) of potassium, the clinician can give 60 mEq (mmol) as the immediate-release potassium liquid, and the other 60 mEq (mmol) can be given through the IV route (20 mEq/100 mL/h [mmol/100 mL/h] in three doses). When giving large potassium doses, serum monitoring should be performed following the administration of half the dose to guide the need for additional potassium. This can also help avoid the development of hyperkalemia.

In the rare circumstances when cardiac arrest from hypokalemia is imminent, IV bolus dosing of potassium 10 mEq (mmol) over 5 minutes can be initiated and repeated once, if necessary.[20]

Alternative Therapies

Potassium-sparing diuretics are a viable alternative to chronic exogenous potassium supplementation, especially when patients are concomitantly receiving medications that are known to deplete potassium (eg, diuretics). Spironolactone inhibits the effect of aldosterone in the distal convoluted tubule of the kidney, thereby decreasing potassium elimination in the urine. Spironolactone is especially effective as a potassium-sparing agent in patients with primary or secondary hyperaldosteronism. Amiloride and triamterene are reasonable second-line agents that act by blocking tubular epithelial sodium channels, leading to decreased renal potassium excretion.

Spironolactone is available as 25-, 50-, and 100-mg tablets. The usual starting dose is 25 to 50 mg daily and can be titrated to a maximum dose of 400 mg/day. The potassium-retaining effects generally take 48 hours to be evident. Principle adverse medication reactions include hyperkalemia, gynecomastia, breast tenderness, and impotence in men. Triamterene is available as 50- and 100-mg capsules. The usual starting dose is 50 mg twice daily, which can be titrated to 100 mg twice daily. Triamterene is also available as a combination product with hydrochlorothiazide (37.5/25 mg, 50/25 mg, or 75/50 mg) and is commonly used for the treatment of hypertension. Common adverse medication reactions include hyperkalemia, sodium depletion, and metabolic acidosis. The usual starting dose of amiloride is 5 mg daily; however, 10 mg can be given in those with severe hypokalemia. This is also available as a combination product with hydrochlorothiazide 50 mg. The most common adverse medication reactions are hyperkalemia and metabolic acidosis.

Concomitant use of potassium supplementation with potassium-sparing diuretics is generally not necessary, but when used there is a risk of hyperkalemia, especially in patients with CKD or diabetes mellitus.

Evaluation of Therapeutic Outcomes

Serum potassium concentrations should be monitored regularly while the patient is receiving potassium supplementation. For ambulatory patients receiving prophylactic potassium supplementation during diuretic therapy, the serum potassium and magnesium concentrations, as well as kidney function should be monitored every 1 to 2 months. In hospitalized patients receiving oral therapy for mild hypokalemia, the potassium concentration should be monitored every 2 to 3 days. If it does not increase by at least 1 mEq/L (mmol/L) within 96 hours, the clinician should suspect concomitant magnesium depletion. Patients receiving IV potassium supplementation require close ECG monitoring if the infusion rate is greater than 20 mEq/h (mmol/h): doses greater than this should be administered only in the presence of continuous ECG monitoring. Additionally, the patient should have serum potassium concentrations obtained halfway through, and 30 minutes following completion of the total potassium dose to guide further potassium administration. Finally, the patient should be assessed for adverse medication reactions such as pain at the infusion site or phlebitis.

Clinical Bottom Line

Hypokalemia is a frequent medical condition caused by both biological processes as well as medication therapy. While mild hypokalemia is frequently asymptomatic, severe hypokalemia can cause fatal cardiac dysrhythmias, particularly in patients with underlying cardiac disease. Patients receiving medications that cause potassium wasting (eg, thiazide or loop diuretics) should be closely followed for the development of hypokalemia and appropriate potassium supplementation should be started when necessary. Generally oral potassium is sufficient for the management of mild hypokalemia; IV potassium should be reserved for severe deficiency, and its use should be monitored closely.

HYPERKALEMIA

Hyperkalemia, defined as a serum potassium concentration greater than 5 mEq/L (mmol/L), can be further classified according to its severity: mild hyperkalemia (5.1-5.9 mEq/L [mmol/L]), moderate hyperkalemia (6-7 mEq/L [mmol/L]), and severe hyperkalemia (above 7 mEq/L [mmol/L]).[19]

Epidemiology

⑤ Hyperkalemia is much less common than hypokalemia. In fact, if all patients with AKI and CKD were excluded, the prevalence of hyperkalemia would be less than 1% in the rest of the population. The incidence of hyperkalemia in hospitalized patients is highly variable, ranging from 1% to 10%.[21] The incidence of hyperkalemia has increased over time likely from the aging of the population, increased prevalence of CKD and diabetes mellitus, and increased use of medications that inhibit the renin-angiotensin-aldosterone system.[22] Severe hyperkalemia occurs more commonly in older adults with impaired kidney function who have been receiving chronic oral potassium supplementation.

Etiology and Pathophysiology

Hyperkalemia develops when potassium intake exceeds excretion (true hyperkalemia) (ie, elevated total-body stores) or when the transcellular distribution of potassium is disturbed (ie, normal total-body stores). The four primary causes of hyperkalemia—(a) increased potassium intake, (b) decreased potassium excretion, (c) tubular unresponsiveness to aldosterone, and (d) redistribution of potassium into the extracellular space—are discussed further.

Hyperkalemia Associated with Increased Potassium Intake

Hyperkalemia in this setting is almost always associated with impaired kidney function. Patients with stage 4 or 5 CKD and dialysis patients who are noncompliant with dietary potassium restrictions often present with life-threatening hyperkalemia. Dietary potassium restrictions are difficult to adhere to since many foods that are considered part of a healthy diet contain potassium. Another common dietary source associated with the development of hyperkalemia is potassium chloride salt substitutes. Many dialysis patients are instructed to use salt substitutes to avoid excessive sodium intake in an attempt to control volume overload. These patients unwittingly become hyperkalemic because these products contain approximately 10 to 15 mEq (mmol) potassium per gram or 200 mEq (mmol) per tablespoon. Finally, some over-the-counter herbal and alternative medicine products may contain large amounts of potassium. It is thus essential for patients with CKD to receive education regarding dietary sources of potassium as well as information on the potassium content of herbal products when available.

Hyperkalemia Associated with Decreased Renal Potassium Excretion

Normally functioning kidneys excrete 90% of the daily potassium intake. Therefore, when the kidney is unable to excrete potassium appropriately, as in AKI and stage 4 to 5 CKD, potassium is retained and often results in hyperkalemia. Finally, because aldosterone is responsible for potassium excretion via the kidney cortical collecting duct, medications and diseases that inhibit this process contribute to hyperkalemia.[23]

Severe hyperkalemia is more common in AKI than in CKD because patients are often hypercatabolic and have underlying disorders, such as rhabdomyolysis or tumor lysis syndrome, which result in release of potassium from injured or lysed cells.[24] Severe hyperkalemia is rare in stable stage 1 to 4 CKD, perhaps because of enhanced GI and renal potassium excretion.[25] Additionally, hyperkalemia directly stimulates renal potassium excretion through an effect that is independent of, and additive to, that of aldosterone.[26] Renal excretion of potassium is also inhibited by various endocrine disorders, including adrenal insufficiency, Addison disease, and selective hypoaldosteronism. All of these disorders involve a decreased production of aldosterone, which results in the retention of potassium.

Several medications have profound effects on the kidney's ability to regulate potassium. These include five medication classes in particular: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin-II receptor blockers (ARBs), direct renin inhibitors, mineralocorticoid receptor antagonists (MRAs) and other potassium-sparing diuretics, and prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs (NSAIDs). Although hyperkalemia is typically dose-dependent, the rates of hyperkalemia may range from 2% to 10%.[27,28] Finerenone (Kerendia®), a non-steroidal MRA FDA-approved for use in patients with diabetic nephropathy, should not be initiated in patients with a serum potassium greater than 5 mEq/L (mmol/L) and should be withheld if the serum potassium rises above 5.5 mEq/L (mmol/L).[29] It has a novel mechanism of action compared to other medications in the class such as spironolactone and eplerenone but similar rates of hyperkalemia.[30] Other commonly used medications that can cause hyperkalemia are β-blockers, digoxin, cyclosporine, tacrolimus, trimethoprim–sulfamethoxazole, and heparin.

Tubular Unresponsiveness to Aldosterone

Sickle cell anemia, systemic lupus erythematosus, and amyloidosis can produce a defect in renal tubular potassium secretion, possibly as the result of an alteration in the aldosterone-binding site.

Redistribution of Potassium into the Extracellular Space

The efflux of potassium from within the cell into the extracellular space, which is associated with no change in total-body potassium stores, is often observed in the presence of metabolic acidosis, diabetes mellitus, CKD, or lactic acidosis. β-Blockers can also result in a transcellular potassium shift.

The serum potassium concentration can also be falsely elevated in some conditions and not reflect the actual in vivo potassium concentration, that is, pseudohyperkalemia. Pseudohyperkalemia occurs most commonly in the setting of extravascular hemolysis of red blood cells. When a blood specimen is not processed promptly and cellular destruction occurs, intracellular potassium is released into the serum. It can also occur in conditions of thrombocytosis or leukocytosis. If severe hyperkalemia is found in a patient who is asymptomatic with an otherwise normal laboratory report, the hyperkalemia is most likely pseudohyperkalemia, and a repeat blood sample should be collected. Truly elevated potassium concentrations are normally associated with other laboratory abnormalities such as low carbon dioxide (acidosis) or elevated blood urea nitrogen and creatinine concentrations (indicating impaired kidney function).

CLINICAL PRESENTATION: Hyperkalemia

General

- Related to the effects of excessive potassium on neuromuscular, cardiac, and smooth muscle cell function.

Symptoms

- Frequently asymptomatic.
- The patient might complain of heart palpitations or skipped heartbeats.

Signs

- ECG changes (Fig. 70-1)

Laboratory Tests

- Serum potassium concentration above 5.0 mEq/L (mmol/L) is diagnostic.

FIGURE 70-1

The earliest electrocardiographic manifestation of hyperkalemia is an increase in the rate of ventricular repolarization, which results in a peaking of the T wave at serum potassium concentrations of ~5.5 to 6 mEq/L (mmol/L) (*B*), relative to the normal ECG presentation (*A*). Further increases in the serum potassium concentration above 6 mEq/L (mmol/L) result in conduction delays through the His-Purkinje system, the atrial myocardium, and the ventricular myocardium. The ECG manifestations of these conduction delays and the sequence in which they occur are a widening of the PR interval (*C*), delay through the His-Purkinje system, a loss of the P wave (*D*), delay through the atrial myocardium, a widening of the QRS complex (*E*), and delay through the ventricular myocardium. Finally, there is a merging of the QRS complex with the T wave (*F*), which results in a sine-wave appearance.

Treatment

Desired Outcomes

The goals of therapy for the treatment of hyperkalemia are to antagonize adverse cardiac effects, reverse signs and symptoms that are present, and return the serum and total-body stores of potassium to normal. The optimal treatment approach is dependent on the severity of hyperkalemia, the rapidity of its development, and the patient's clinical condition. Cardiac instability and arrhythmias, which can be life-threatening, may be present especially when serum potassium is above 6 mEq/L (mmol/L). Although ECG changes are directly proportional to the serum potassium concentration and its rate of increase, they may not be present in all patients. Asymptomatic patients with mild hyperkalemia usually require no specific therapy other than dietary education to control intake, and monitoring of serum potassium daily if an inpatient or weekly if an outpatient to assure resolution.

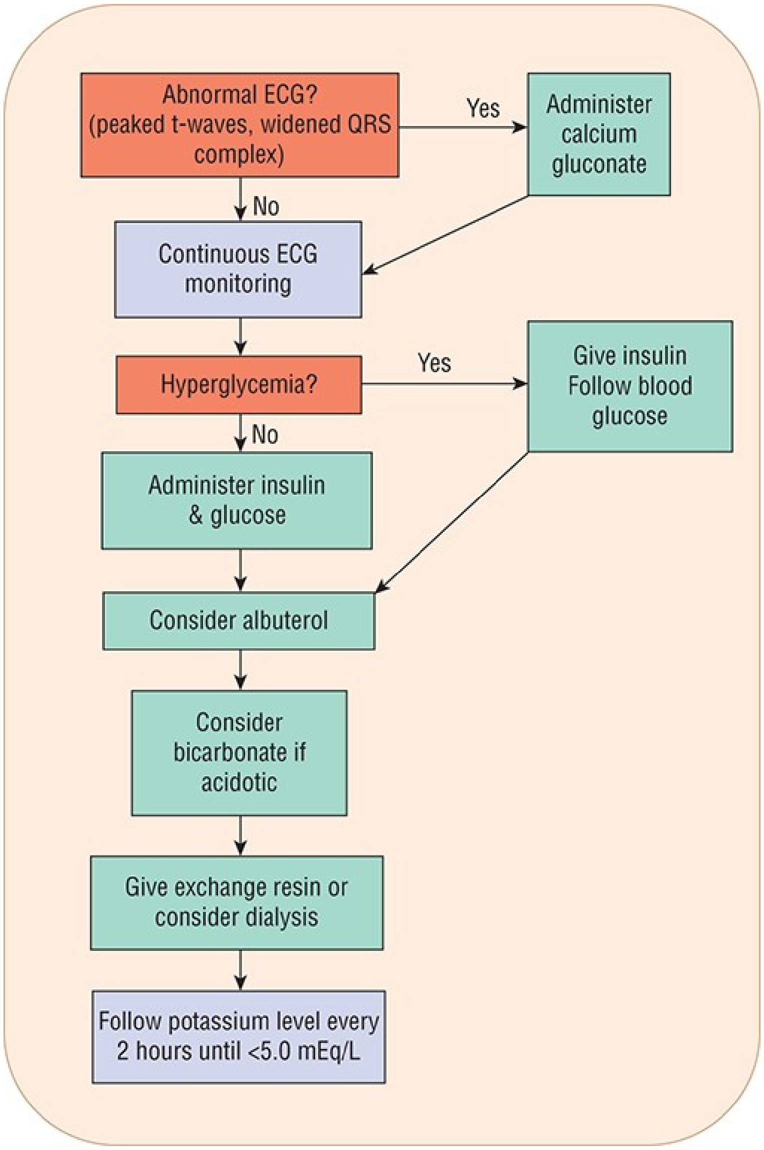
Severe hyperkalemia (above 7 mEq/L [mmol/L]) or moderate hyperkalemia (6-6.9 mEq/L [mmol/L]), when associated with clinical symptoms or ECG changes, requires immediate treatment. Initial treatment should be focused on antagonism of the cardiac membrane actions of hyperkalemia (eg, administration of calcium). Secondarily, one should attempt to decrease extracellular potassium concentration by promoting its intracellular movement (eg, with insulin, β_2-receptor agonists, or sodium bicarbonate) or enhance its removal from the body by hemodialysis: the oral administration of cation-exchange resins, and/or the use of loop diuretics may also be considered in some patients. In any case, the underlying cause of hyperkalemia should be identified and reversed, and exogenous potassium must be withheld.

General Approach to Treatment

A treatment approach for patients with hyperkalemia is outlined in Fig. 70-2. In patients who have acute ECG changes, IV calcium should be administered to raise the threshold potential and stabilize the myocardium.[31] At the same time, the serum potassium concentration should be rapidly decreased to below 5 mEq/L (mmol/L) within minutes by administering medications that cause an intracellular shift of potassium, followed by the initiation of those that increase the elimination of potassium from the body.[31] If the patient is asymptomatic, rapid correction may not be necessary and will likely depend on the clinical context associated with the rise in serum potassium concentration. If one anticipates the need to reduce total-body potassium stores, an ion exchange resin that results in removal of potassium from the body over several hours to days may be initiated shortly after the emergent care has been instituted. An IV loop diuretic can be used to facilitate potassium removal through diuresis in patients who are hypervolemic and have preserved kidney function.[31]

FIGURE 70-2

Treatment approach for hyperkalemia. (Serum potassium of 5.0 mEq/L is equivalent to 5.0 mmol/L.)



Abnormal ECG? (peaked t-waves, widened QRS complex)
Yes
Administer calcium gluconate
No
Continuous ECG monitoring
Hyperglycemia?
Yes
Give insulin Follow blood glucose
No
Administer insulin & glucose
Consider albuterol
Consider bicarbonate if acidotic
Give exchange resin or consider dialysis
Follow potassium level every 2 hours until <5.0 mEq/L

Nonpharmacologic Therapy

Hemodialysis patients who ingest foods supplemented with glycyrrhetinic acid, the active ingredient in licorice, may be better able to maintain serum potassium concentrations within the normal range.[32,33] Glycyrrhetinic acid inhibits the enzyme 11β-hydroxy-steroid dehydrogenase II, thereby increasing cortisol availability in the colon. The net result is enhanced potassium elimination in the feces. Other nonpharmacologic therapies, specifically available for dialysis-dependent patients are the tailoring of their intermittent dialysis or hemofiltration therapy to include a low potassium dialysate to enhance the removal of potassium (see Chapter 64). Emergency dialysis can be considered in patients with acute kidney injury who have persistent ECG changes or insufficient response to therapies that cause intracellular potassium shifts, although the optimal time to initiate dialysis is not known.[34]

Pharmacologic Therapy

There are several medication therapy options to lower the serum potassium concentration. The optimal regimen for a given patient is dependent on the rapidity and degree of lowering that is necessary. Table 70-5 provides an overview of the available therapies and their respective onset and duration of action.

TABLE 70-5

Therapeutic Alternatives for the Management of Hyperkalemia

Medication	Dose	Route of Administration	Onset/Duration of Action	Acuity	Mechanism of Action	Expected Result
Calcium gluconate or chloride	1 g	IV over 5-10 minutes	1-2 min/10-30 min	Acute	Raises cardiac threshold potential	Reverses electrocardiographic effects
Furosemide	20-40 mg	IV	5-15 min/4-6 h	Acute	Inhibits renal Na^+ reabsorption	Increased urinary K^+ loss
Regular insulin	5-10 units	IV or subcut	30 min/2-6 h	Acute	Stimulates intracellular K^+ uptake	Intracellular K^+ redistribution
Dextrose 10%	1,000 mL (100 g)	IV over 1-2 hours	30 min/2-6 h	Acute	Stimulates insulin release	Intracellular K^+ redistribution
Dextrose 50%	50 mL (25 g)	IV over 5 minutes	30 min/2-6 h	Acute	Stimulates insulin release	Intracellular K^+ redistribution
Sodium bicarbonate	50-100 mEq (50-100 mmol)	IV over 2-5 minutes	30 min/2-6 h	Acute	Raises serum pH	Intracellular K^+ redistribution
Albuterol	10-20 mg	Nebulized over 10 minutes	30 min/1-2 h	Acute	Stimulates intracellular K^+ uptake	Intracellular K^+ redistribution
Hemodialysis	4 hours	N/A	Immediate/variable	Acute	Removal from serum	Increased K^+ elimination
Sodium polystyrene sulfonate	15-60 g	Oral or rectal	1 h/variable	Nonacute	Resin exchanges Na^+ for K^+	Increased K^+ elimination
Patiromer	8.4-25.2 g	Oral	Hours/variable	Nonacute	Resin exchanges Ca^{++} for K^+	Increased K^+ elimination
Sodium zirconium cyclosilicate	5-15 g	Oral	1 h/variable	Nonacute	Resin exchanges Na^+ for K^+	Increased K^+ elimination

While specific treatment recommendations vary, it is generally accepted that asymptomatic patients with potassium concentrations below 6 mEq/L (mmol/L) can be treated conservatively. In patients with normal kidney function or those with stage 3 or 4 CKD, this typically involves the administration of furosemide to promote urinary potassium excretion. When given IV at a dosage of 40 to 80 mg, urine flow usually increases within minutes and persists for approximately 4 to 6 hours. Oral furosemide can also be used, keeping in mind the IV:PO dose ratio (1:2) and delayed onset of action compared to IV. Close monitoring of the patient's volume status and other electrolyte concentrations is required while the patient is receiving furosemide. Of note, the effectiveness of diuretics in treating hyperkalemia has not been studied in a randomized, controlled fashion.

In symptomatic patients, or in those with severe hyperkalemia, emergency care is indicated. Initial therapy in this setting is the administration of IV calcium chloride or gluconate 1 g to treat or prevent life-threatening arrhythmias.[31] Calcium antagonizes the cardiac membrane effect of hyperkalemia by reducing the electrical threshold potential for cardiac myocytes and reverses ECG changes within minutes. IV calcium should not be given to patients receiving digoxin as it can lead to digoxin toxicity. Its duration of action is 30 to 60 minutes, and it can be repeated as needed based on ECG findings. IV calcium can be given as either the chloride or gluconate salt; each is available as a 10% solution by weight. Calcium chloride provides approximately three times more calcium than equal volumes of the gluconate salt; however, it can cause tissue necrosis if extravasation occurs. For this reason, calcium gluconate is more commonly administered, with the standard dose being 1 g IV bolus over 5 to 10 minutes.

Rapid correction of hyperkalemia may necessitate the administration of medications that result in an intracellular shift of potassium, such as insulin and dextrose, sodium bicarbonate, and a β_2-adrenergic receptor agonist (eg, albuterol). The treatment of choice depends on the underlying medical disorders accompanying hyperkalemia. For example, in patients with concomitant metabolic acidosis, a sodium bicarbonate bolus or infusion of 50 to 100 mEq (mmol) is the preferred therapy. Sodium bicarbonate helps correct the metabolic acidosis by raising the extracellular pH, in addition to causing a rapid intracellular potassium shift. It should be noted that sodium bicarbonate is much less effective when hyperkalemia is not related to metabolic acidosis.[1] Sodium bicarbonate is also less effective in patients with end-stage renal disease (ESRD), in whom a decrease in serum potassium may not be seen for as long as 4 hours. Use caution in patients sensitive to volume changes as sodium bicarbonate can also lead to hypernatremia and volume overload. Administration of a rapid-acting (eg, Insulin lispro 10 units IV) or regular insulin (10 units IV) and dextrose (10% or 50%) is an effective method of reducing potassium. Insulin increases the activity of the Na^+-K^+-ATPase pump, thereby intracellularly shifting potassium. Insulin therapy results in a reduction in potassium concentration of 0.6 to 1 mEq/L (mmol/L) that is sustained for up to 2 hours.[35] Glucose should be given with insulin because hypoglycemia can develop as a result of the effects of the insulin therapy.[36] Alternative dosing strategies, such as low dose (eg, regular insulin 5 units) or weight-based regimens have been studied to combat hypoglycemia with varying results and cannot be routinely recommended.[37–39] A lower dose insulin strategy may be appropriate for patients with severe kidney impairment.[40] β_2-adrenergic agonists have a dual mechanism for lowering serum potassium. First, they stimulate the Na^+-K^+-ATPase pump to promote intracellular potassium uptake. Second, they stimulate pancreatic β-receptors to increase insulin secretion. Albuterol can be administered via IV (0.5 mg given over 15 minutes) or via nebulizer (10-20 mg nebulized over 10 minutes). It should be noted that injectable albuterol is not available in the United States.

In patients with ESRD, decreases in the serum potassium concentration of 0.6 mEq/L (mmol/L) and 1 mEq/L (mmol/L) can be anticipated after inhalation of 10 and 20 mg of albuterol, respectively. Notice that the doses of inhaled albuterol used for hyperkalemia are at least four times higher than those typically used for bronchospasm, so adverse medication reactions are of greater concern. Adverse medication reactions include tachycardia, tremors, palpitations, mild anxiety, and increase blood glucose.[35] Furthermore, as many as 40% of patients may be resistant to the hypokalemic effects of albuterol and patients already receiving a nonselective β_2-receptor antagonist may not respond. Inconsistent bioavailability via the inhaled route must also be considered, as it could lead to potential over- or underdosing and an unpredictable response.

While not a fast-acting treatment based on pharmacokinetics, one ion exchange resin, sodium polystyrene sulfonate (SPS), is regularly used in hospitalized patients with acute hyperkalemia. It has been used in hospitalized patients for over 60 years. SPS (Kayexalate®) is a cation-exchange resin that can be administered orally or rectally by enema. SPS is available in powder form or prepackaged as a 33% sorbitol suspension. The usual oral SPS dose is 15 to 60 g in the 33% sorbitol suspension. The oral route is more effective than the enema and is better tolerated by patients. As the resin passes through the intestines, each gram of SPS exchanges 1 mEq (mmol) of sodium for 1 mEq (mmol) of potassium, which is in a relatively higher concentration in the large intestine. The onset of action of SPS is within 1 hour, and it can be repeated every 4 hours as needed. The medication should be separated from other oral medications by at least 3 hours as it may bind to and decrease the effectiveness of many oral medications.[41] The sorbitol component of the suspension promotes the excretion of the cationically modified potassium exchange resin by inducing diarrhea. SPS contains a large amount of sodium (100 mg [4.1 mEq or mmol] per gram of SPS) and package labeling advises against its use in patients who cannot tolerate even small increases in sodium loads.[42]

Colonic necrosis is associated with the use of SPS.[43,44] In 2009, the FDA mandated a boxed warning for SPS due to reports of colonic necrosis and other serious GI toxicities.[42] The GI toxicities were believed to be associated with the 70% sorbitol; however, GI toxicity has also occurred with administration of 33% sorbitol solution. Toxicity appears to occur most commonly in patients who have undergone GI surgery or with current or history of bowel dysfunction. Therefore, the 33% sorbitol product is preferred over the 70% sorbitol product, rectal administration should be avoided, and use is contraindicated in patients with bowel dysfunction.

Several years ago, a Cochrane Review evaluated the emergency treatment of hyperkalemia and provided evidence for the efficacy of inhaled and nebulized β-agonists and IV insulin and glucose.[45] The combination of nebulized β-agonists with IV insulin and glucose appeared to be more effective than either agent alone. The meta-analysis results were equivocal for IV bicarbonate, and notably, SPS was not effective by 4 hours. Clinicians should exercise caution when extrapolating these findings to clinical practice. Nonetheless, the Cochrane database review corroborates the approach detailed in Fig. 70-2. Frequently, the management of hyperkalemia will be based on the clinician's personal judgment or institutional protocols. For example, the large majority (95%) of patients being treated for hyperkalemia in academic teaching hospitals receive SPS, with far fewer receiving insulin and IV calcium, and less than 10% of patient receive bicarbonate, albuterol, or hemodialysis.[46] In many emergency departments, insulin/glucose is the most commonly used agent and multimodal therapy is employed for treating initial serum potassium concentrations above 6 mEq/L (mmol/L).[47]

In nonhospitalized patients who have experienced chronic increases in serum potassium concentration, long-term management of hyperkalemia is focused on dietary restriction of potassium-rich foods and supplements, reducing and avoiding medications that impair potassium excretion in the kidney, and using diuretics or other medications to counteract the effects of medications that increase serum potassium concentrations. Medications used for chronic conditions that are known to cause hyperkalemia include NSAIDs, ACEIs, ARBs, direct renin inhibitors, and MRAs. These typically result in asymptomatic hyperkalemia without the need for emergent therapies. To prevent hyperkalemia, clinicians may attempt to lower the dose or switch to another medication without hyperkalemia as an adverse medication reaction (eg, calcium channel blocker). However, medications that inhibit the renin–angiotensin–aldosterone system (RAAS) have significant beneficial effects on morbidity and mortality in patients with chronic diseases such as diabetes mellitus, heart failure, and CKD. Therefore, reducing or avoiding the use of these medications to prevent hyperkalemia is not often appropriate. The use of a combination of ACEI and ARB is generally avoided due to the increased risk of hyperkalemia.[48] Mineralocorticoid receptor antagonists have a different mechanism of action and their use in combination with an ACEI or ARB is considered acceptable. In particular, finerenone has been shown to lower the rates of CKD progression and cardiovascular events in diabetic nephropathy when added to other RAAS inhibitors.[49,50] This provides the strongest evidence to date for the combination of MRA with an ACEI or ARB in patients with diabetic nephropathy and will likely expand the number of patients on dual RAAS inhibitors. As a third-generation non-steroidal MRA, it has equal distribution into cardiac and renal tissues, compared to spironolactone and eplerenone which favor distribution into renal tissue.[30] The starting dose of finerenone is 10 or 20 mg once daily based on eGFR and serum potassium with a target dose of 20 mg once daily. It should not be used with strong CYP3A4 inhibitors and inducers. The most common adverse medication reactions of finerenone are hyperkalemia, hypotension, and hyponatremia.[29] The extent of hyperkalemia is greater with a combination ACEI and MRA than a combination ACEI and ARB in patients with diabetic nephropathy, suggesting an extrarenal mechanism of this adverse medication reaction from MRAs.[51]

To allow for continued use of RAAS inhibitors, especially in patients prone to hyperkalemia, ion exchange resins may be used. A daily dose of SPS in patients with CKD receiving RAAS inhibitors effectively lowers and maintains serum potassium in the normal range.[52,53] Two other cation exchange agents, patiromer and sodium zirconium cyclosilicate, are available as alternatives to SPS in outpatients with hyperkalemia. Patiromer (Veltassa®) is a nonabsorbable polymer that exchanges calcium for potassium in the distal colon to increase the fecal elimination of potassium. The medication effectively achieves and maintains normokalemia in adults with stage 3 or 4 CKD on stable doses of RAAS inhibitors.[54,55] The most common adverse medication reactions of patiromer include constipation, hypomagnesemia, and diarrhea. The usual dose of patiromer is 8.4 to 25.2 g once daily. Patiromer contains sorbitol to increase medication stability, but at amounts 5- to 10-fold lower than SPS in sorbitol.[25] It should not be used to treat life-threatening hyperkalemia due to its delayed onset of action.[56] Additionally, patiromer can bind to many oral medications, which could lead to decreased absorption of other mediations and loss of efficacy. Therefore, it is recommended to administer other oral medications at least 3 hours before or after patiromer.[56]

Sodium zirconium cyclosilicate (ZS-9, Lokelma®) is a nonabsorbable inorganic compound that selectively exchanges sodium for potassium throughout the entire intestinal tract. The medication effectively decreases serum potassium concentrations as soon as 1 hour after administration of the first dose and for up to 48 hours after administration, with an average decrease of approximately 1 mEq/L (mmol/L) for the 10 g dose.[57,58] ZS-9 exhibits an acute onset of action, but is not FDA approved for emergency treatment of life-threatening hyperkalemia. It is the only ion exchange resin that is approved for treatment of hyperkalemia in patients with ESRD on hemodialysis. The most common adverse medication reaction ZS-9 is edema, likely from the exchange of sodium for potassium. The starting dose is 10 g three times daily for 48 hours followed by 5 to 15 g once daily. The dosing in patients on hemodialysis is 5 to 15 g on nondialysis days. Like SPS and patiromer, ZS-9 must be separated from other oral medications but the separation time is shorter at 2 hours.[59]

Evaluation of Therapeutic Outcomes

The frequency and rigor with which one evaluates patients to ascertain if they have achieved the desired therapeutic outcomes depends on the severity and acuity of hyperkalemia. For example, cautious waiting is more common for those with mild or moderate asymptomatic hyperkalemia compared to those with acute symptomatic, severe hyperkalemia. Many medications such as ACEIs, ARBs, direct renin inhibitors, spironolactone and finerenone result in asymptomatic hyperkalemia and changes in dosage or to a different agent may be all that is warranted. In patients with normal kidney function, once these medications are initiated and the dose titrated, clinicians should check the potassium concentration at least monthly. More frequent monitoring of serum potassium is warranted with combination MRA and either ACEI or ARB. For those patients with impaired kidney function, monitoring should be biweekly until the dose is stabilized.

In patients who have acute symptomatic hyperkalemia (eg, ECG changes), frequent potassium concentration and ECG monitoring is warranted. The patient should receive continuous ECG telemetry monitoring until the serum potassium concentration decreases below 5 mEq/L (mmol/L), and the ECG abnormalities resolve. Similarly, while the patient is receiving emergent therapy, serial serum potassium concentrations should be obtained hourly until the potassium concentration decreases below 5 mEq/L (mmol/L). For patients who receive insulin and dextrose therapy for hyperkalemia, blood glucose monitoring should be performed hourly or more frequently if patients demonstrate signs and symptoms of hypoglycemia. For patients who receive large doses of sodium bicarbonate therapy for hyperkalemia, an arterial blood gas or serum chemistry profile should be obtained to assess their acid-base status. Furthermore, the patient should be evaluated for signs of fluid overload secondary to the high sodium load. Patients receiving albuterol therapy should be questioned regularly regarding the development of palpitations and tachycardia. The patient's medication records should be reviewed to assure the patient is not receiving medication therapy that increases the serum potassium concentration. Furthermore, the patient should be questioned regarding the occurrence of diarrheal stool output.

Clinical Bottom Line

Hyperkalemia commonly occurs in patients with reduced kidney function or other metabolic disturbances. It can rapidly evolve into a medical emergency; therefore, prompt identification and appropriate pharmacotherapy are needed. In patients with mild hyperkalemia, potassium binding resins or loop diuretics may be useful and should be used as first-line therapy. In severe hyperkalemia with ECG changes, IV calcium should be given to protect against cardiac dysrhythmias. Additionally, rapid-acting therapies such as IV insulin and β_2-adrenergic agonists are indicated to move potassium intracellularly.

DISORDERS OF MAGNESIUM HOMEOSTASIS

Magnesium plays a central role in cellular function and is an important cofactor in more than 300 biochemical reactions in the body, especially those systems that are dependent on adenosine triphosphate. Mitochondrial function, protein synthesis, cell membrane function, parathyroid hormone secretion, and glucose metabolism are just a few important functions affected by magnesium.[60] It is the fourth most abundant extracellular cation and the second most abundant intracellular cation, after potassium. Disorders of magnesium homeostasis are commonly encountered in clinical situations and most frequently are manifested as alterations in cardiovascular and neuromuscular functions. Life-threatening conditions such as paralysis and cardiac arrhythmias can occur, making the proper recognition and treatment of these problems of paramount importance. Altered magnesium balance also plays a key role in chronic disease states such as diabetes mellitus, CKD, osteoporosis, development of kidney stones, as well as heart and vascular disease.[61]

Magnesium is principally distributed in bone (67%) and muscle (20%). Because of its predominantly intracellular distribution, measurement of magnesium in the extracellular compartment may not accurately reflect the total-body magnesium content. The majority of magnesium in the extracellular fluid is in the ionized form as only 30% is bound to serum proteins. The normal range for serum magnesium is 1.4 to 1.8 mEq/L (1.7-2.3 mg/dL or 0.70-0.95 mmol/L).

The recommended daily dietary magnesium intake for adults is approximately 420 mg/day and 320 mg/day for men and women, respectively. The maintenance of magnesium homeostasis depends on the balance between intake and output. Ingested magnesium (30%-40%) is absorbed in the small bowel. The absorption of magnesium decreases as the dietary intake increases. Reductions in absorption have also been noted in older adults and those with CKD. A small amount is present in intestinal secretions and reabsorbed in the sigmoid colon. The kidneys play a major role in maintaining magnesium balance. Approximately 95% of the filtered magnesium is reabsorbed, thus in most patients less than 5% is excreted in the urine.[51] Renal magnesium handling is unique in that approximately 20% of the filtered magnesium is reabsorbed in the proximal tubule; the majority (up to 70%) of reabsorption occurs in the thick ascending limb of the loop of Henle. This explains why loop diuretics often cause profound urinary magnesium wasting. The remaining 10% is reabsorbed in the distal convoluted tubule.[62] Unlike most other important electrolytes, there is no hormonal regulation of the distribution of magnesium between bone and circulating or intracellular magnesium pools. Because of this, both hypomagnesemia and hypermagnesemia commonly occur.

CLINICAL PRESENTATION: Hypomagnesemia

General

- The dominant organ systems affected by hypomagnesemia are the neuromuscular and cardiovascular systems.

Symptoms

- Neuromuscular symptoms such as tetany, twitching, and generalized convulsions are common.
- Cardiac symptoms include heart palpitations.

Signs

- Neuromuscular: Presence of Chvostek sign, Trousseau sign, tremor, and tetany.
- Cardiovascular: Cardiac arrhythmias (ventricular fibrillation, torsade de pointes, or digoxin-induced arrhythmias), sudden cardiac death, and hypertension can be present. ECG abnormalities include widened QRS complex and peaked T waves with mild hypomagnesemia; and prolonged PR interval, progressive widening of QRS complex, and flattened T waves with moderate to severe hypomagnesemia.

Laboratory Tests

- Serum magnesium concentration less than 1.4 mEq/L (1.7 mg/dL [0.70 mmol/L]). Serum potassium and calcium concentrations can also be low.

HYPOMAGNESEMIA

Epidemiology

Hypomagnesemia is a common problem in both ambulatory and hospitalized patients. Although the exact prevalence is difficult to estimate, up to 65% of ICU patients may be magnesium-deficient. Although serum magnesium concentrations are not a reliable index of total-body magnesium content, they remain the primary diagnostic tool to evaluate body stores.

Hypomagnesemia is associated with an increase in mortality in critically ill patients. The incidence and associated risks of hypomagnesemia in hospitalized general medicine patients, even though they are at an increased risk of hypomagnesemia given the presence of comorbidities such as heart failure, CKD, and diabetes mellitus. Hypomagnesemia may be observed in as many as 20% of hospitalized general medicine patients and is associated with increased mortality.[63]

Etiology and Pathophysiology

⑥ Hypomagnesemia is usually associated with disorders of the intestinal tract or kidney.[64] Medications or conditions that interfere with intestinal absorption or increase renal excretion of magnesium can result in hypomagnesemia (Table 70-6). Decreased intestinal absorption as a result of small bowel disease is the most common cause of hypomagnesemia worldwide. These disorders include regional enteritis, radiation enteritis, ulcerative colitis, acute and chronic diarrhea, pancreatic insufficiency and other malabsorptive syndromes, small-bowel bypass surgery, and chronic laxative misuse. Proton pump inhibitors, especially when used chronically, can cause hypomagnesemia through impaired intestinal absorption. Hypomagnesemia is commonly associated with alcohol use disorder, where the etiology is multifactorial, including reduced intake, pancreatic insufficiency, chronic vomiting and diarrhea, and urinary magnesium wasting.

TABLE 70-6

Causes of Hypomagnesemia

GI

- Reduced intake
    - Protein-calorie malnutrition
    - Prolonged parenteral fluid administration without magnesium
    - Alcohol use disorder
- Reduced absorption
    - Primary hypomagnesemia
    - Malabsorption syndromes (eg, tropical sprue, celiac disease, radiation enteritis, or intestinal lymphectasia)
    - Short-bowel syndrome (eg, small-bowel resection or ileal bypass)
    - Pancreatic insufficiency
    - Proton pump inhibitors (long-term use)
- Increased loss
    - Excessive vomiting
    - Prolonged nasogastric suction
    - Excessive laxative use
    - Intestinal and biliary fistulas
    - Prolonged diarrhea (ulcerative colitis, Crohn disease, or cancer of the colon)

Kidney

- Primary tubular disorders
    - Primary renal magnesium wasting
    - Bartter syndrome
    - Renal tubular acidosis
    - Diuretic phase of acute tubular necrosis
    - Postobstructive diuresis
    - Postrenal transplant diuresis
- Glomerulonephritis
- Pyelonephritis
- Drug-induced renal losses
    - Aminoglycosides
    - Amphotericin B
    - Cyclosporine
    - Tacrolimus
    - Diuretics
    - Digitalis
    - Cisplatin
    - Pentamidine
    - Foscarnet

Hormone-induced renal losses
  Primary hyperparathyroidism
  Hyperthyroidism
  Aldosteronism
  "Hungry bone syndrome" after parathyroidectomy

Internal redistribution
Diabetic ketoacidosis Glucose, amino acid, or insulin administration Massive blood transfusion (citrate) Pancreatitis with lipedema (magnesium soap)
Other
Excessive sweating and lactation Hypercalcemia and hypercalciuria Phosphate depletion Chronic alcohol use disorder Extracellular fluid volume expansion

Primary renal magnesium wasting can be caused by a defect in renal tubular magnesium reabsorption, or inhibition of sodium reabsorption in those segments in which magnesium transport follows passively. The former condition is associated with hypercalciuria, nephrolithiasis, and progressive kidney disease, while the latter is associated with Gitelman and Bartter syndromes.[64] Much more common than these is renal magnesium wasting secondary to thiazide and loop diuretics. Other commonly used medications that can cause renal magnesium wasting include aminoglycosides, amphotericin B, cyclosporine, digoxin, tacrolimus, cisplatin, pentamidine, and foscarnet.[65]

Treatment

Desired Outcomes

The treatment goals in the management of hypomagnesemia are (a) resolution of the signs and symptoms, (b) restoration of normal magnesium concentrations, (c) correction of concomitant electrolyte abnormalities, and (d) identification and correction of the underlying cause of magnesium depletion.

General Approach to Treatment

Magnesium supplementation can be administered by the oral, intramuscular (IM), or IV route. The severity of the magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus administration is associated with flushing, sweating, and a sensation of warmth; thus, bolus administration should be avoided if possible. Additionally, because calcium forms a complex with the sulfate moiety, which is then excreted, large amounts of IV magnesium sulfate should be administered with caution to patients with hypocalcemia, as it can further exacerbate calcium deficiency.[61] It is widely accepted that 8 to 12 g of magnesium sulfate be administered, in divided doses, in the first 24 hours followed by 4 to 6 g/day for 3 to 5 days to adequately replete body stores in those with severe hypomagnesemia.[66] Even if severe magnesium depletion is present, approximately 50% of the administered dose is excreted in the urine. Consequently, magnesium replacement should be performed over 3 to 5 days, and continued supplementation should be provided for patients unable to eat. Table 70-7 lists the commonly used magnesium oral supplements and their respective elemental magnesium content.

TABLE 70-7

Common Magnesium Products and Their Elemental Magnesium Content

Product	Elemental Magnesium Content
Magnesium aspartate hydrochloride	122 mg in 1,230 mg dietary supplement granules
Magnesium carbonate	121 mg in 500 mg capsule
Magnesium chloride	64 mg in each 535 mg tablet
Magnesium citrate	48 mg in each 5 mL of the oral solution
Magnesium gluconate	27 mg in a 500 mg tablet
Magnesium glycerophosphate	97 mg in 1 g tablet
Magnesium hydroxide	167 mg in a 400 mg tablet or 5 mL oral suspension
Magnesium lactate	84 mg in an 84 mg tablet
Magnesium oxide	242 mg in a 400 mg tablet

Nonpharmacologic Therapy

There are no nonpharmacologic options for the management of hypomagnesaemia.

Pharmacologic Therapy

It is controversial whether all asymptomatic patients require magnesium supplementation when serum magnesium concentration falls below the normal range. In particular, for patients with type 2 diabetes mellitus, hypomagnesemia contributes to diabetic complications by affecting glucose transport and insulin secretion and utilization. Indeed, oral magnesium supplementation in patients with type 2 diabetes mellitus and hypomagnesemia improves insulin sensitivity and metabolic control.[67] On the other hand, hypomagnesemia may be a consequence of diabetes mellitus. Possible mechanisms of hypomagnesemia in these patients include reduced GI absorption, enhanced renal excretion secondary to an increased filtered magnesium load and tubular flow, and reduced tubular reabsorption. Metabolic abnormalities such as hypokalemia, hypophosphatemia, and metabolic acidosis may also contribute to its development.[68] While it seems reasonable to provide a supplement for diabetic patients with low serum magnesium concentrations, improved clinical outcomes have not been demonstrated.

Should treatment be warranted, those patients with serum magnesium concentrations greater than 1 mEq/L (1.2 mg/dL [0.5 mmol/L]) can be treated with oral supplements. Oral supplementation is preferred because magnesium uptake is a slow process that may require prolonged administration. Several magnesium products are available, including magnesium-containing antacids or laxatives, comprising a variety of magnesium salts in tablet or capsule formulations. Many of the oral products contain little magnesium, which necessitates three or four doses per day. As expected, diarrhea is the most common dose-limiting adverse medication reactions of oral therapy, which can greatly reduce patient compliance. Therefore, sustained-release magnesium products are preferred as they not only improve patient compliance but also reduce the occurrence of GI adverse medication reactions.

In patients with severe magnesium depletion (serum concentrations less than 1 mEq/L [1.2 mg/dL; 0.5 mmol/L]) or if signs and symptoms are present regardless of the serum concentration, IV magnesium should be administered. A dose of 4 to 6 g in 50 to 100 mL (maximum concentration 1 g/10 mL) should be administered in divided doses over 12 to 24 hours and repeated as necessary in order to maintain magnesium concentrations above 1 mEq/L (1.2 mg/dL [0.5 mmol/L]). Doses of 2 to 4 g in 50 mL infused over 1 hour are frequently used clinically; however, these result in transient benefit because of the extensive renal excretion and usually have to be repeated daily over 3 to 5 days for adequate repletion. Therapy should be continued until the signs and symptoms have completely resolved. In patients with impaired kidney function, some have reduced the does by 25% to 50%.

Evaluation of Therapeutic Outcomes

In patients with acute, asymptomatic mild-to-moderate hypomagnesemia, serum magnesium concentrations should be obtained at least daily during their hospitalization. Patients receiving oral magnesium therapy should be questioned regarding GI tolerance and the occurrence of diarrhea. Patients being treated for symptomatic severe hypomagnesemia should have their serum magnesium concentration monitored hourly until the serum concentration reaches 1.5 mEq/L (1.8 mg/dL [0.75 mmol/L]) and the symptoms resolve. At that point, the serum magnesium concentration can be monitored every 6 to 12 hours for the next 24 hours while receiving magnesium supplementation. Once the magnesium concentration is stable in the normal range, a concentration can be obtained daily. It should be reiterated that it typically takes 3 to 5 days to fully replete total-body magnesium stores. Patients receiving oral magnesium-containing antacids or supplements should be asked regularly about the occurrence of diarrhea.

Clinical Bottom Line

Hypomagnesemia is generally associated with kidney or GI tract disorders. Patients with mild, chronic magnesium loss, oral magnesium preparations can be used; however, the dose-limiting adverse medication reaction is diarrhea. For more severe hypomagnesemia, IV magnesium sulfate can be safely administered. Repeated doses may be needed as IV magnesium is rapidly eliminated in urine. In such cases, close monitoring of serum magnesium concentrations is needed.

HYPERMAGNESEMIA

Epidemiology

7 Hypermagnesemia (serum magnesium greater than 2 mEq/L [2.4 mg/dL; 1 mmol/L]) is a rare occurrence that is generally seen in patients with stage 4 or 5 CKD when magnesium intake exceeds the excretory capacity of the kidneys. Older adults are prone to hypermagnesemia because of their reduced GFR and because of their tendency to consume magnesium-containing antacids and vitamins.

Etiology and Pathophysiology

Because magnesium excretion decreases as GFR declines, serum magnesium concentrations tend to increase in patients with moderate-to-severe CKD. Indeed, magnesium concentrations steadily increase as the GFR decreases below 30 mL/min/1.73 m^2. As long as the patient maintains a normal diet, the serum magnesium concentration typically stabilizes at approximately 2.5 mEq/L (3 mg/dL [1.25 mmol/L]). If patients with stage 4 or 5 CKD are taking concomitant magnesium-containing antacids, the serum concentration can approach 6 mEq/L (7.3 mg/dL [3 mmol/L]), a value associated with signs and symptoms of toxicity. Critically ill patients with multiorgan system failure receiving enteral or parenteral nutrition are also prone to develop hypermagnesemia. Finally, the parenteral treatment of eclampsia with magnesium sulfate can lead to hypermagnesemia. Table 70-8 lists other causes of hypermagnesemia.

TABLE 70-8

Causes of Hypermagnesemia

Decreased renal excretion
Acute kidney injury
CKD with exogenous intake
Excessive intake
Treatment of toxemia of pregnancy
Ureteral irrigants (hemiacidrin)
Cathartics
Other
Lithium therapy
Hypothyroidism
Milk-alkali syndrome
Addison disease
Viral hepatitis
Acute diabetic ketoacidosis

CKD, chronic kidney disease.

Clinical Presentation

⑧ The signs and symptoms of hypermagnesemia reflect magnesium's action on the neuromuscular and cardiovascular systems.[66,69] The main symptoms include lethargy, confusion, dysrhythmias, and muscle weakness. Symptoms are rare when the serum concentration is below 4 mEq/L (4.9 mg/dL [2 mmol/L]) (Fig. 70-3).

FIGURE 70-3

Clinical findings associated with hypermagnesemia. (Serum magnesium concentrations in mmol/L can be determined by multiplying the serum magnesium value expressed in mEq/L by 0.5.)

Treatment

Desired Outcome

The goals of therapy are to (a) reverse the neuromuscular and cardiovascular manifestations of hypermagnesemia, (b) decrease the magnesium concentration toward normal values, and (c) identify and treat the underlying cause of hypermagnesemia.

Nonpharmacologic Therapy

There are no nonpharmacologic options for the management of hypermagnesemia.

Pharmacologic Therapy

There are three primary means of treating hypermagnesemia: (a) reduce magnesium intake, (b) enhance elimination of magnesium, and (c) antagonize the physiologic effects of magnesium. The optimal treatment regimen for the management of hypermagnesemia depends on the severity of the patient’s signs and symptoms and the degree of serum concentration elevation. IV elemental calcium doses of 100 to 200 mg directly antagonize the neuromuscular and cardiovascular effects of hypermagnesemia. Oral calcium is not effective because of its relatively poor bioavailability and slow onset of action. The clinical effect of calcium is immediate, but the effect is transient; hence, repeated IV doses of 100 to 200 mg of elemental calcium (eg, 2 g of calcium gluconate) might need to be administered hourly until the signs or symptoms abate and the magnesium concentration is normalized. Supportive care with cardiac pacing, vasopressors, and mechanical ventilation can be necessary in life-threatening situations. In patients with normal kidney function or those with stage 1, 2, or 3 CKD, forced diuresis with 0.45% NaCl and loop diuretics can promote magnesium elimination. An initial IV bolus of furosemide 40 mg or a similar equivalent can be used. Subsequent dosing can be determined based on the patient's clinical response. Patients with CKD can require long-term loop diuretic therapy to maintain adequate fluid and electrolyte balance. In patients with ESRD receiving dialysis, their hemodialysis prescription should be changed to employ magnesium-free dialysate.

Evaluation of Therapeutic Outcomes

Patients who are receiving IV calcium salts for the treatment of severe, symptomatic hypermagnesemia should have their serum magnesium concentration evaluated hourly until symptoms abate and the magnesium concentration decreases below 4 mg/dL (3.3 mEq/L [1.64 mmol/L]). Furthermore, the patient should be continuously monitored to detect ECG changes. In patients with CKD who can produce urine, forced diuresis with saline and furosemide should reduce the serum magnesium concentration within 6 to 12 hours. Close monitoring of the urine output and physical examination for signs of volume overload are important. Emergency hemodialysis will usually correct the hypermagnesemia within 4 hours and is a reasonable option for those who are receiving hemodialysis. To prevent further episodes of hypermagnesemia, the patient should receive dietary education regarding foods and beverages that contain large quantities of magnesium (Table 70-9).

TABLE 70-9

Magnesium Content of Selected Foods

Food	Elemental Magnesium Content per Serving (mg)
Halibut, cooked, 3 oz (85 g)	90
Almonds, dry roasted, 1 oz (28 g)	80
Spinach, boiled, one-half cup (~125 mL)	78
Cashews, dry roasted, 1 oz (28 g)	74
Peanuts, oil roasted, one-fourth cup (~60 mL)	63
Shredded wheat cereal, two large biscuits	61
Soymilk, plain, or vanilla, 1 cup (~250 mL)	61
Black beans, cooked, one-half cup (~125 mL)	60
Edamame, shelled, cooked, one-half cup (~125 mL)	50
Peanuts, dry roasted, 1 oz (28 g)	50
Peanut butter, smooth, 2 tablespoons (~30 mL)	49
Bread, whole wheat, 2 slices	46
Avocado, cubed, 1 cup (~250 mL)	44
Potato, baked with skin, 3.5 oz (~100 g)	43
Yogurt, plain, low fat, 8 oz (~225 g)	42
Rice, brown, cooked, one-half cup (~125 mL)	42
Breakfast cereals, fortified with 10% of the daily value for magnesium	40
Instant oatmeal, 1 cup (~250 mL)	36
Kidney beans, canned, one-half cup (~125 mL)	35
Banana, 1 medium	32

Clinical Bottom Line

Hypermagnesemia is generally associated with advanced CKD. Severe hypermagnesemia can result in neurologic symptoms or cardiac dysrhythmias. Should these symptoms occur, IV calcium can counteract these effects. Forced diuresis with saline and loop diuretics is useful in lowering magnesium in patients with mild to moderate kidney disease; hemodialysis should be reserved for patients with ESRD.

ABBREVIATIONS

ACEI	angiotensin-converting enzyme inhibitor
AKI	acute kidney injury
ARB	angiotensin-II receptor blocker
CKD	chronic kidney disease
ECG	electrocardiogram
ESRD	end-stage renal disease
FDA	Food and Drug Administration
GFR	glomerular filtration rate
GI	gastrointestinal
IM	intramuscular
IV	intravenous
MRA	mineralocorticoid receptor antagonist
NSAID	nonsteroidal anti-inflammatory drug
RAAS	renin–angiotensin–aldosterone system
SPS	sodium polystyrene sulfonate

SELF-ASSESSMENT QUESTIONS

1. Which of the following treatments for hyperkalemia works by preventing intestinal absorption of potassium?

   A. Albuterol

   B. Patiromer

   C. Sodium bicarbonate

   D. Insulin + dextrose

2. Which of the following medications would be expected to result in hyperkalemia?

   A. Hydrochlorothiazide

   B. Fosinopril

   C. Furosemide

   D. Albuterol

3. A patient has the following symptoms on presentation: lethargy, decreased deep tendon reflexes, somnolence. She *most likely* has which of the following conditions?

   A. Hypokalemia

  B. Hyperkalemia

  C. Hypomagnesemia

  D. Hypermagnesemia

4. Which of the following is *immediate first line* therapy for hyperkalemia associated with ECG changes?

  A. Furosemide 40 mg PO

  B. Calcium gluconate 1 gram IV

  C. Hemodialysis

  D. Regular insulin 10 Units IV

5. Which of the following statements regarding IV potassium is *correct*?

  A. The infusion rate should not exceed 20 mEq/hour (20 mmol/hour) in a peripheral line

  B. IV potassium is preferred in all hospitalized patients

  C. Potassium should be diluted in dextrose 5% water

  D. Continuous ECG monitoring is always necessary when infusing potassium

6. Dividing the total daily dose of oral potassium supplements into smaller doses helps to minimize which of the following adverse medication reactions?

  A. Itching

  B. Hypoglycemia

  C. GI upset

  D. Muscle cramps

7. A patient presents with Trousseau sign. She *most likely* has which of the following conditions?

  A. Hypokalemia

  B. Hyperkalemia

  C. Hypomagnesemia

  D. Hypermagnesemia

8. Which of the following is *true* of sodium polystyrene sulfonate (SPS) compared to patiromer?

  A. Both exchange potassium for sodium in the intestines

  B. Both must be separated from other oral medications by 3 hours

  C. Both are known to cause colonic necrosis

  D. Both are commonly used to treat life-threatening hyperkalemia

9. Your patient develops hyperkalemia (without ECG changes) as a result of severe metabolic acidosis. Which of the following is considered the *first-*

line treatment option?

A. IV calcium gluconate

B. Insulin + dextrose

C. Albuterol

D. Sodium bicarbonate

10. Which of the following is a possible adverse medication reaction of intravenous magnesium replacement therapy?

A. Diarrhea

B. Kidney failure

C. Muscle pain

D. Flushing

11. A patient on a general medicine floor has morning labs drawn, which include a serum potassium is 3.2 mEq/L (mmol/L) and serum magnesium is 0.9 mg/dL (0.74 mEq/L; 0.37 mmol/L). He is ordered for and given 40 mEq of liquid potassium chloride by mouth. Repeat labs drawn 8 hours later show a serum potassium of 3.4 mEq/L (mmol/L) and serum magnesium 0.9 mg/dL (0.74 mmol/L; 0.37 mmol/L). What is the *most appropriate* therapy to order for this patient to increase his serum potassium?

A. Potassium chloride 60 mEq PO

B. Magnesium sulfate 2 grams IV

C. Potassium chloride 40 mEq IV

D. Magnesium oxide 400 mg PO

12. Proton pump inhibitors cause hypomagnesemia through which mechanism?

A. Hormone-induced renal losses

B. Internal redistribution

C. Reduced gastrointestinal intake

D. Reduced gastrointestinal absorption

13. Disorders of potassium primarily affect the cardiovascular system and which other system?

A. Neuromuscular

B. Renal

C. Skeletal

D. Gastrointestinal

14. Which of the following dramatically affects potassium homeostasis?

A. Respiratory acidosis

B. Insulin secretion

C. Circulating acetylcholine

D. Cortisol production

15. Which of the following patients is *most likely* to develop hypermagnesemia?

A. A 45-year-old alcoholic receiving treatment for acute alcohol withdrawal

B. A 60-year-old patient receiving treatment for fungemia with amphotericin B

C. A 35-year-old patient with ESRD who has missed the past two sessions of dialysis

D. A 17-year-old patient with newly diagnosed hypothyroidism

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Patiromer is one of three available potassium binders that decreases total body potassium. See the "Hyperkalemia (Pharmacologic Therapy)" and Table 70-1 for more information.

2. **B.** Angiotensin-converting enzyme inhibitors prevent renal potassium excretion and can lead to hyperkalemia. See the Hyperkalemia Associated with Decreased Renal Potassium Excretion" and "Hyperkalemia (Pharmacologic Therapy)" sections for more information.

3. **D.** The main symptoms of hypermagnesemia include lethargy, confusion, dysrhythmias, and muscle weakness. See the "Hypomagnesemia (Clinical Presentation)" section and Fig. 70-3 for more information.

4. **B.** In patients with hyperkalemia and ECG changes, IV calcium is the first line therapy. See the "General Approach to Therapy" and "Pharmacologic Therapy" sections and Fig. 70-2 for more information.

5. **A.** Generally, doses of 10 to 20 mEq (mmol) of potassium chloride are safe when administered through a peripheral vein over an hour. See the "Pharmacologic Therapy" section for more information.

6. **C.** Smaller doses of oral potassium supplements helps to minimize the common adverse medication reaction of GI upset. See the "Pharmacologic Therapy" section for more information.

7. **C.** Clinical presentations of hypomagnesemia can include specific neuromuscular effects such as Chvostek and Trousseau signs. See the "Disorders of Magnesium Homeostasis (Clinical Presentation Hypomagnesemia)" section for more information.

8. **B.** Administration of both SPS and patiromer must be separated from other oral medications by at least 3 hours. See the "Pharmacologic Therapy" section for more information.

9. **D.** In patients with concomitant metabolic acidosis sodium bicarbonate is the preferred therapy to treat hyperkalemia. See the "Pharmacologic Therapy" section and Fig. 70-2 for more information.

10. **D.** IV magnesium bolus administration is associated with flushing, sweating, and a sensation of warmth. See the "General Approach to Treatment" section for more information.

11. **B.** In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia first. See the "Etiology and Pathophysiology" and "Pharmacologic Therapy" sections for more information.

12. **D.** Proton pump inhibitors, especially when used chronically, can cause hypomagnesemia through impaired intestinal absorption. See the "Hypomagnesemia (Etiology and Pathophysiology)" section for more information.

13. **A.** Potassium disorders primarily affect the neuromuscular and cardiac systems. See the "Clinical Presentation (Hyperkalemia)" section for more information.

14. **B.** Insulin stimulates the cellular Na^+-K^+-ATPase pump to increase intracellular potassium transport in response to increasing serum potassium. See the “Control of Potassium Homeostasis” section for more information.

15. **C.** Decreased renal excretion is a common cause of hypermagnesemia. See the “Hypermagnesemia (Etiology and Pathophysiology)” section and Table 70-8 for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 71: Acid–Base Disorders

Anne M. Tucker; Tami N. Johnson

KEY CONCEPTS

KEY CONCEPTS

① The lung plays a central role in acid–base homeostatic regulation through an increase or decrease in respiration to regulate the partial pressure of CO_2 in the blood (PCO_2); an increased respiratory rate (RR) eliminates more CO_2, reduces the PCO_2 in the blood, and results in a reduced carbonic acid concentration and increased pH; the opposite occurs with decreased respiration.

② The kidney also plays a central role in the regulation of acid–base homeostasis through the excretion or reabsorption of filtered bicarbonate (HCO_3^-), the excretion of metabolic fixed acids, and the generation of new HCO_3^-.

③ Each acid–base disturbance has a compensatory response that attempts to correct the HCO_3^--to-$PaCO_2$ ratio toward normal and mitigate the change in pH. The respiratory compensatory response to metabolic disturbances is initiated rapidly, whereas the metabolic compensatory response to respiratory disturbances occurs more slowly.

④ Metabolic acidosis and metabolic alkalosis are generated by a primary change in the serum bicarbonate concentration. In metabolic acidosis, bicarbonate is lost or a nonvolatile acid is gained, whereas metabolic alkalosis is characterized by a gain in bicarbonate or a loss of nonvolatile acid.

⑤ Arterial blood gases (ABGs), along with serum electrolytes, physical findings, medical and medication history, and the clinical condition of the patient, are the primary tools to determine the cause of an acid–base disorder and to design and monitor a course of therapy.

⑥ Renal tubular acidosis (RTA) refers to a group of disorders characterized by impaired tubular renal acid handling despite normal or near-normal glomerular filtration rates. These patients often present with hyperchloremic metabolic acidosis.

⑦ Primary therapy of most acid–base disorders must include treatment or removal of the underlying cause, not just correction of the pH and electrolyte disturbances.

⑧ Potassium supplementation is always necessary for patients with chronic metabolic acidosis, as the bicarbonaturia resulting from alkali therapy increases renal potassium wasting.

⑨ Effective treatment of the underlying cause of some organic acidoses (eg, ketoacidosis) can result in bicarbonate regeneration within hours thus mitigating the need for alkali therapy.

⑩ A patient's response to volume replacement can be predicted by the urine chloride concentration and permits the differential diagnosis of metabolic alkalosis.

⑪ Loss of gastric acid from vomiting or nasogastric suctioning may lead to hypochloremia and hyperbicarbonatemia and may often lead to a metabolic alkalosis.

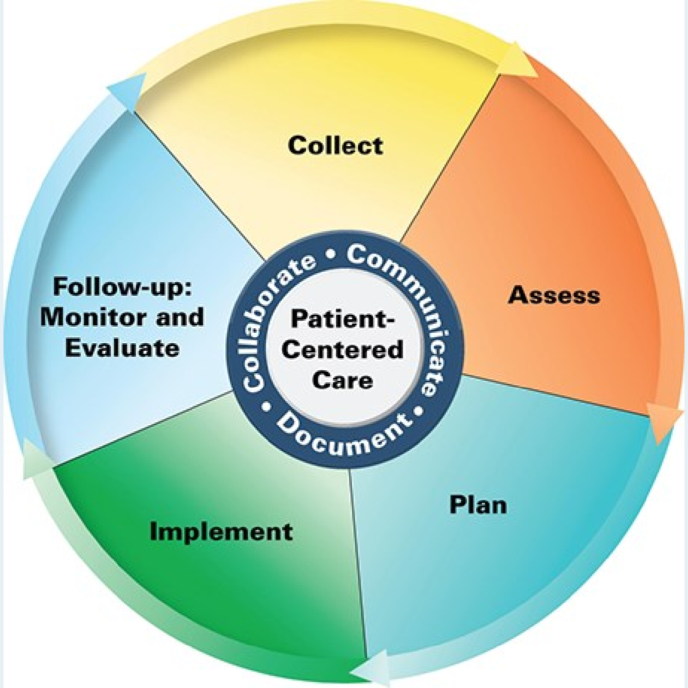
⑫ Aggressive loop diuretic therapy can produce a metabolic alkalosis, and the accompanying hypokalemia.

⑬ Management of metabolic alkalosis due to excessive renal acid excretion usually consists of treatment of the underlying cause of mineralocorticoid excess. In patients in whom the mineralocorticoid excess cannot be corrected, chronic pharmacologic therapy may be required.

⑭ In most cases of acute respiratory acidosis, such as following cardiopulmonary arrest, sodium bicarbonate therapy is not indicated and can be detrimental. Blood gas analysis and the clinical status of the patient should guide therapy.

PATIENT CARE PROCESS

Patient Care Process for Acid–Base Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient medical history (eg, prior acid–base disorder, chronic lung or kidney disease, diabetes mellitus)
- Current medications, including intravenous (IV) fluids (see Tables 71-5, 71-6, 71-7, 71-11, 71-12, and 71-13, 71-14)
- Social history (alcohol use, potential for toxic ingestion)
- Objective data

  Blood pressure (BP), heart rate (HR), RR, height, weight, oxygen saturation

  Labs including arterial blood gases (ABG), serum electrolytes (including serum CO_2), serum creatinine (SCr), serum osmolality, serum lactate, blood glucose, urine chloride

  Current fraction of inspired oxygen (FiO_2)

Assess

- $[HCO_3^-]$ on ABG and electrolyte panel to verify accuracy
- Serum anion gap (SAG)
- Presence of acidemia (pH less than 7.35) or alkalemia (pH greater than 7.45) (see Figure 71-3 and Table 71-4)
- Presence of respiratory disturbance (alteration in $PaCO_2$) or metabolic disturbance (alteration in HCO_3^-)
- Compensatory response (Table 71-8)

- Change in [Cl^-] with change in [Na^+]
- Presence of elevated SAG metabolic acidosis (Table 71-6, 71-7)

  Presence of elevated serum osmolar gap and/or serum lactate

- Presence of metabolic alkalosis (Table 71-11)

  Presence of urine chloride less than 10 mEq/L (mmol/L) or greater than 20 mEq/L (mmol/L)

- Presence of respiratory acid–base disorder (see Tables 71-12, 71-13, 71-14)

Plan[*]

- Identification and removal (when possible) of potential cause(s) for the acid–base disorder
- Fluid, electrolyte, or medication therapy (see Tables 71-9 and 71-10, and Figure 71-4)

  Monitoring parameters may include a repeat RR, oxygen saturation, ABG, and serum electrolytes; repeat SCr, serum osmolality, serum lactate, blood glucose, and/or urine chloride

- Referrals to other providers when appropriate (eg, nephrologist, pulmonologist)

Implement[*]

- Patient education (eg, purpose of treatment, dietary and lifestyle modification, medication-specific information, medication administration instructions) when the acid–base disorder is chronic
- Schedule follow-up when appropriate

Follow-up: Monitor and Evaluate

- Resolution of acid–base disorder symptoms
- Presence of adverse medication reactions (if acid–base disorder treated with medication)
- Patient adherence to treatment plan using multiple sources of information

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Acid–Base Balance & Blood Gas Interpretation” in the 2019 National Council Licensure Examination (NCLEX) Review [available at https://youtu.be/kh62SRovgrI]. This 10-minute video provides a brief overview of acid–base balance, disturbances, compensation, and interpretation. This video is useful to enhance student understanding regarding the assessment of acid–base disorders in the patient care process.

INTRODUCTION

Acid–base disorders are common and often serious disturbances that can result in significant morbidity and mortality. This chapter reviews the mechanisms responsible for the maintenance of acid–base balance and the laboratory analyses that aid clinicians in their assessment of acid–base disorders. The pathophysiology of the four primary acid–base disturbances is presented, evidence-based therapeutic options are reviewed, and management guidelines to optimize the outcome of patients with one of these disorders are presented. Given that medications are a frequent cause of acid–base abnormalities and that acid–base abnormalities are often preventable, clinicians must anticipate medication-related problems to avoid or minimize the clinical consequences of acid–base disorders, and when necessary, design appropriate treatment regimens.

ACID–BASE CHEMISTRY

An acid (in this equation, hydrochloric acid) is a substance that can *donate* protons (hydrogen ion [H^+]):

$$\text{(Acid)HCl} \rightarrow H^+ + \text{Chlorideion } (Cl^-)$$

(Acid)HCl→H++Chlorideion (Cl-)

A base (in this equation, ammonia [NH_3]) is a substance that can *accept* protons (hydrogen ion [H^+]):

$$\text{(Ammonia)}NH_3 + H^+ \rightarrow NH_4^+ \text{(base)}$$

(Ammonia)NH3+H+→NH4+(base)

The acid–base pairs commonly encountered in clinical practice are listed in Table 71-1.

TABLE 71-1

Acid–Base Pairs

Carbonic acid/bicarbonate	H_2CO_3/HCO_3^-
Monobasic/dibasic phosphate	H_2PO_4/HPO_4^-
Ammonium/ammonia	NH_4^+/NH_3
Lactic acid/lactate	$H_6C_3O_2/H_5C_3O_2^-$

The acidity of body fluids is quantified in terms of the hydrogen ion concentration. By convention, the degree of acidity is expressed as pH, or the negative logarithm (base 10) of the hydrogen ion concentration. Thus, hydrogen ion concentration and pH are inversely related. Normally, the pH of blood is maintained at 7.4 ([H^+] of 4×10^{-8} M) with a range of 7.35 to 7.45. A pH of less than 6.7 ([H^+] of 2×10^{-7} M), representing a fivefold increase in hydrogen ion concentration, or greater than 7.7 ([H^+] of 2×10^{-8} M), representing a 50% decrease in hydrogen ion concentration, is considered incompatible with life.

The hydrogen ion concentration in blood may not be indicative of that in other body compartments. For example, the pH within cells, within the cerebrospinal fluid, or on the surface of bone can all be altered without causing an alteration in blood pH.[1] Recognizing this caveat, the acid–base status of the body is usually analyzed based on measurement of blood pH. Alterations in blood pH serve as the basis for the diagnosis of acid–base disorders.

The dissociation of acid–base pairs is an equilibrium reaction. This allows the relationship between hydrogen ion concentration or pH and the relative concentrations of the acid and base to be described mathematically in terms of the dissociation constant for the acid–base buffer pair. When expressed as a logarithmic relationship, where pK is the negative logarithm of the dissociation constant K, this is known as the Henderson–Hasselbalch equation:

$$pH = pK + \log([\text{base}]/[\text{acid}])$$

pH=pK+log([base]/[acid])

BUFFERS

The ability of a weak acid and its corresponding anion (base) to resist change in the pH of a solution with the addition of a strong acid or base is referred to as *buffering*. An acid–base pair is most efficient in functioning as a buffer at a pH close to its pK. The principal extracellular buffer is the carbonic acid/bicarbonate (H_2CO_3/HCO_3^-) system. Other physiologic buffers include plasma proteins, hemoglobin, and phosphates. The complex buffering of biologic fluids can be analyzed based on a single buffer pair because the isohydric principle requires that all buffer systems remain in chemical equilibrium.

The carbonic acid/bicarbonate buffer system plays a unique role in acid–base homeostasis. In addition to being the most abundant extracellular buffer, the components of this buffer pair exist under dynamic regulation by the body. In the presence of carbonic anhydrase, carbonic acid, $[H_2CO_3]$, is in equilibrium with carbon dioxide (CO_2) gas. Changes in pulmonary ventilation that alter the partial pressure of CO_2 (PCO_2) in the blood regulate the carbonic acid level in the blood. Conversely, the bicarbonate concentration is independently regulated by the kidney. Because the p*K* for the carbonic acid/bicarbonate system is 6.1, the relationship between pH, carbonic acid, and bicarbonate concentrations can be described by the Henderson–Hasselbalch equation. The concentration of carbonic acid is directly proportional to the amount of CO_2 dissolved in blood, which is equal to the product of PCO_2 and its solubility in physiologic fluids ($PCO_2 \times 0.03$ for PCO_2 expressed in mm Hg or $PCO_2 \times 0.226$ for PCO_2 expressed in kPa). This term can, therefore, be substituted into the equation below in place of $[H_2CO_3]$.

$\mathrm{pH}=6.1+\log([\mathrm{HCO}_3^-]/[\mathrm{H_2CO_3}])$pH=6.1+log([HCO3-]/[H2CO3])

$\mathrm{pH}=6.1+\log([\mathrm{HCO}_3^-]/[\mathrm{PCO}_2\times 0.03])$ for PCO_2 in mm HgpH=6.1+log([HCO3-]/[PCO2×0.03]) for PCO2 in mm Hg

or

$\mathrm{pH}=6.1+\log([\mathrm{HCO}_3^-]/[\mathrm{PCO}_2\times 0.226])$ for PCO_2 in kPapH=6.1+log([HCO3-]/[PCO2×0.226]) for PCO2 in kPa

Thus, hydrogen ion concentration and pH are determined not by the absolute amounts of bicarbonate and PCO_2 present but by their ratio.[2] Under normal physiologic conditions, the kidneys maintain the serum bicarbonate at approximately 24 mEq/L (mmol/L), whereas the lungs maintain the PCO_2 at approximately 40 mm Hg (5.3 kPa). The normal physiologic pH is thus 7.4:

$$\mathrm{pH}=6.1+\log[24/(0.03\times 40)] \quad (\text{or } \mathrm{pH}=6.1+\log[24/0.226\times 5.3]) \\ \mathrm{pH}=6.1+1.3=7.4$$
pH=6.1+log[24/(0.03×40)](or pH=6.1+log[24/0.226×5.3])pH=6.1+1.3=7.4

If, in response to an acid load, the serum bicarbonate concentration decreases to 12 mEq/L (mmol/L), then the predicted pH would be:

$[\mathrm{HCO}_3^-]=12\,\mathrm{mEq/L}$ (mmol/L)[HCO3-]=12mEq/L (mmol/L)
$PCO_2=40$ mm Hg(5.3 kPa)PCO2=40 mm Hg(5.3 kPa)
$\mathrm{pH}=6.1+\log[12/0.03\times 40]$ orpH=6.1+log[12/0.03×40] or
$\mathrm{pH}=6.1+\log([12/(0.226\times 5.3)])$pH=6.1+log([12/(0.226×5.3)])
$\mathrm{pH}=6.1+1.0=7.1$pH=6.1+1.0=7.1

However, the normal respiratory response to an acid load is hyperventilation. As a result, if the PCO_2 decreased to approximately 26 mm Hg (3.5 kPa), then the change in pH would be less:

$[\mathrm{HCO}_3^-]=12$ mEq/L(mmol/L)[HCO3-]=12 mEq/L(mmol/L)

$PCO_2=26$ mm Hg (3.5 kPa)PCO2=26 mm Hg (3.5 kPa)
$\mathrm{pH}=6.1+\log[12/0.03\times 26]$pH=6.1+log[12/0.03×26]
or $\mathrm{pH}=6.1+\log[12/(0.226\times 3.5)]$or pH=6.1+log[12/(0.226×3.5)]
$\mathrm{pH}=6.1+1.19=7.29$pH=6.1+1.19=7.29

Thus, the physiologic regulation of both PCO_2 and $[HCO_3^-]$ permits the carbonic acid/bicarbonate system to provide more effective buffering of the extracellular fluids (ECFs) than could be achieved on the basis of chemical buffering alone.

REGULATION OF ACID–BASE HOMEOSTASIS

Cellular metabolism results in the production of large quantities of hydrogen that need to be excreted to maintain acid–base balance. In addition, small amounts of acid and alkali are also presented to the body through the diet. The bulk of acid production is in the form of CO_2, with the average adult producing approximately 15,000 mmol of CO_2 each day from the catabolism of carbohydrate, protein, and fat.[2] When respiratory function is normal, the amount of CO_2 produced metabolically is equal to the amount lost by respiration, and the blood CO_2 concentration remains constant.

Digestion of dietary substances and tissue metabolism also result in the production of nonvolatile acids. These acids are derived primarily from the sulfur-containing amino acids cysteine and methionine, as well as from ingested sulfur. In addition, phosphates are generated from the metabolism of proteins and phospholipids. Neutral substances such as glucose can also be incompletely metabolized to intermediates, such as lactic and pyruvic acid, and fatty acids can be incompletely metabolized to acetoacetic acid and β-hydroxybutyric acid. These dietary and metabolic fixed acids are excreted primarily by the kidney to maintain acid–base homeostasis. On average, daily fixed acid excretion is approximately 0.8-1 mEq/kg/day (mmol/kg/day).[3]

Three processes, each of which varies in its onset, collectively maintain acid–base balance: extracellular buffering, ventilatory regulation of carbon dioxide elimination, and kidney regulation of hydrogen ion and bicarbonate excretion. Extracellular buffering occurs rapidly and is the body's first defense against a sudden increase in hydrogen ion concentration. Hyperventilation then results in a decrease in PCO_2, returning blood pH toward normal. Finally, over a period of day(s), the kidney will excrete the excess hydrogen ion and acid–base balance will return to normal.

Extracellular Buffering

The body's buffering system can be divided into three components: bicarbonate/carbonic acid, proteins, and phosphates. The bicarbonate/carbonic acid buffer system is the most abundant of the body's buffers making it the first line of the defense of changes in pH, because (a) there is more bicarbonate present in the ECF than any other buffer component; (b) the supply of CO_2 is unlimited; and (c) the acidity of ECF can be regulated by controlling either the bicarbonate concentration or the PCO_2.

Carbonic acid represents the respiratory component of the buffer pair because its blood concentration is directly proportional to the PCO_2, which is determined by ventilation. Bicarbonate represents the metabolic component because the kidney may alter its concentration by reabsorption, generating new bicarbonate, or altering elimination.[2] The bicarbonate buffer system easily adapts to changes in acid–base status by alterations in ventilatory elimination of acid (PCO_2) and/or renal elimination of base (HCO_3^-).

The phosphate buffer system consists of serum inorganic phosphate (3.5-5 mg/dL [1.13-1.62 mmol/L]), intracellular organic phosphate, and calcium phosphate in bone. Extracellular phosphate is present only in low concentrations, so its usefulness as a buffer is limited; however, as an intracellular buffer, phosphate is more useful. Calcium phosphate in bone is relatively inaccessible as a buffer, but prolonged metabolic acidosis will result in the release of phosphate from bone.

Intracellular and extracellular proteins also act as buffering systems. The charged side chains of amino acids provide the buffering action. Because the concentration of protein is much greater intracellularly than extracellularly, protein is much more important as an intracellular buffer.

Respiratory Regulation

① The second process involved in maintenance of acid–base homeostasis is ventilatory regulation of CO_2 elimination. Both the rate and depth of ventilation can be varied to allow for excretion of CO_2 generated by diet and tissue metabolism. Medullary chemoreceptors in the brainstem sense changes in PCO_2 and pH and modulate the control of breathing. Increasing minute ventilation (the total amount of air exhaled over a 1-minute period), by increasing RR and/or tidal volume (the amount of air exhaled in one breath), will increase CO_2 excretion and decrease the blood PCO_2. Conversely, decreasing minute ventilation decreases CO_2 excretion and increases blood PCO_2. This system rapidly adjusts to changes in acid–base balance.[4]

Kidney Regulation

② Bicarbonate is freely filtered at the glomerulus because it is a small ion. The bicarbonate load delivered to the nephron is approximately 4,500 mEq/day (mmol/day).[2] To maintain acid–base balance, this entire filtered bicarbonate load must be reabsorbed. Bicarbonate reabsorption occurs primarily in the proximal tubule (Fig. 71-1). In the tubular lumen, filtered bicarbonate combines with hydrogen ion, secreted by the apical sodium ion (Na^+)–H^+-exchanger, to form carbonic acid. The carbonic acid is rapidly broken down to CO_2 and water by carbonic anhydrase, an enzyme located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ions that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

FIGURE 71-1

Proximal tubular bicarbonate reabsorption and renal acid secretion. The diagram shows the cellular processes involved in bicarbonate (HCO_3^-) reabsorption and renal acid (H^+) secretion in the lumen of proximal tubule lumen (left), proximal tubular cell (in the middle), and peritubular capillary (on the right). In the tubular lumen, filtered HCO_3^- combines with a H^+ secreted by an apical sodium ion (Na^+)–H^+ exchanger to form carbonic acid (H_2CO_3). Carbonic anhydrase located on the luminal surface of the brush border membrane rapidly breaks down H_2CO_3 to carbon dioxide (CO_2) and water (H_2O). The H_2O is absorbed from the tubular lumen into the cell and then into the peritubular capillary. The CO_2 then diffuses into the proximal tubular cell, where it reforms H_2CO_3 in the presence of intracellular carbonic anhydrase. Within the tubular cell, H_2CO_3 dissociates into H^+ and HCO_3^-. Ammonium ion (NH_4^+) is also produced and excreted into the tubular lumen. The HCO_3^- exits the tubular cell across the basolateral membrane into the peritubular capillary along with Na^+. The H^+ is secreted back into the tubular lumen where it is used to generate additional HCO_3^- through the above process and facilitate urinary acid secretion through formation of NH_4^+ and dihydrogen phosphate ion ($H_2PO_4^-$). The secreted H^+ may also titrate $citrate^{3-}$ to form $Hcitrate^{2-}$ in the tubular lumen which is equivalent to reabsorption of alkali when transported into the tubular cell.

Excretion of metabolic fixed acids and generation of new HCO_3^- are achieved in nearly equal parts by renal ammoniagenesis and distal tubular hydrogen ion secretion. Ammoniagenesis plays a critical role in acid–base homeostasis, with ammonium (NH_4^+) excretion comprising approximately 50% of renal net acid excretion. Ammonium is generated from the deamination of glutamine in the proximal tubule. For each ammonium ion excreted in the urine, one bicarbonate ion is regenerated and returned to the circulation.[2]

Distal tubular hydrogen ion secretion accounts for the remaining 50% of net acid excretion. Although the distal tubule consists of multiple distinct functional segments and cell types, the carbonic anhydrase–containing intercalated cells are primarily responsible for acid–base transport. Specifically, type A intercalated cells function as hydrogen ion secreting cells (Fig. 71-2). In these cells, CO_2 combines with water in the presence of intracellular carbonic anhydrase to form carbonic acid, which dissociates to H^+ and HCO_3^-. The H^+ is actively transported into the tubular lumen by a H^+–adenosine triphosphatase. The bicarbonate exits the cell across the basolateral membrane and enters the circulation.[2]

FIGURE 71-2

Collecting duct acid excretion. The diagram shows the cellular processes involved in acid excretion in the lumen of the collecting duct of the nephron (left), renal collecting duct cell (in the middle), and peritubular capillary (on the right). Hydrogen ion (H^+) and bicarbonate (HCO_3^-) are generated intracellularly from carbon dioxide (CO_2) and water (H_2O) in the presence of intracellular carbonic anhydrase. The H^+ is actively secreted into the tubular lumen for excretion by H^+–adenosine triphosphatase located in the apical (luminal) membrane. The HCO_3^- exits the renal collecting duct cell across the basolateral membrane and enters the peritubular capillary as chloride ion (Cl^-) enters the cell.

ACID–BASE DISTURBANCES

③ ④ Alterations in blood pH are designated by the suffix “-emia”; *acidemia* is an arterial blood pH less than 7.35 and *alkalemia* is an arterial blood pH more than 7.45. The pathophysiologic processes that result in alterations in blood pH are designated by the suffix “-osis.” These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid–base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration, whereas in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid–base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the partial pressure of carbon dioxide from arterial blood ($PaCO_2$). In respiratory acidosis, the $PaCO_2$ is elevated; in respiratory alkalosis, it is decreased. Each disturbance has a compensatory (secondary) response that attempts to correct the HCO_3^--to-$PaCO_2$ ratio toward normal and mitigate the change in pH (Table 71-2). Although the time course of the respiratory compensatory response to metabolic disturbances is rapid, the metabolic compensation for respiratory disturbances is slow. As a result, respiratory disturbances are characterized as acute (minutes to hours in duration), indicating that there has not been sufficient time for metabolic compensation, or chronic (days), indicating that sufficient time for metabolic compensation has elapsed.

TABLE 71-2

Interpretation of Simple Acid–Base Disorders

Acid–Base Disorder	pH	Primary Disturbances	Compensation
Acidosis			
Respiratory	Decrease	Increase $PaCO_2$	Increase HCO_3^-
Metabolic	Decrease	Decrease HCO_3^-	Decrease $PaCO_2$
Alkalosis			
Respiratory	Increase	Decrease $PaCO_2$	Decrease HCO_3^-
Metabolic	Increase	Increase HCO_3^-	Increase $PaCO_2$

CLINICAL ASSESSMENT OF ACID–BASE STATUS

A blood gas is measured to determine not only a patient's acid–base status but also their oxygenation. Under normal circumstances, the pH difference between arterial and mixed venous blood is not clinically significant. However, the oxygenation difference between arterial and mixed venous blood is always substantial. Arterial samples are designated with the letter “a” (eg, partial pressure of oxygen from arterial blood [PaO_2] and $PaCO_2$), whereas mixed venous samples are labeled with the letter “v” or not labeled (eg, partial pressure of oxygen from venous blood [PvO_2] and partial pressure of carbon dioxide from venous blood [$PvCO_2$]). The normal values for arterial and venous blood gases are shown in Table 71-3. Arterial blood reflects how well the blood is being oxygenated by the lungs (an accurate measurement of PaO_2), whereas venous blood reflects how much oxygen tissues are using. Arterial blood rather than venous blood should be used whenever possible because venous blood obtained from an extremity can provide misleading information. If metabolism in the extremity is altered by hypoperfusion, exercise, infection, or some other cause, the difference in the amount of dissolved oxygen between arterial and venous blood can be dramatic. The venous pH and PCO_2 during cardiopulmonary resuscitation might be significantly lower and higher, respectively, than the arterial pH and arterial PCO_2. This indicates a severe tissue acidosis from CO_2 accumulation caused by hypoperfusion.

TABLE 71-3

Normal Blood Gas Values

	Arterial Blood	Mixed Venous Blood
pH	7.40 (7.35-7.45)	7.38 (7.33-7.43)
PO_2	80-100 mm Hg (10.6-13.3 kPa)	35-40 mm Hg (4.7-5.3 kPa)
SaO_2	95% (0.95)	70-75% (0.70-0.75)
PCO_2	35-45 mm Hg (4.7-6.0 kPa)	45-51 mm Hg (6.0-6.8 kPa)
HCO_3^-	22-26 mEq/L (mmol/L)	24-28 mEq/L (mmol/L)

HCO_3^-, bicarbonate; PCO_2, partial pressure of carbon dioxide; PO_2, partial pressure of oxygen; SaO_2, saturation of arterial oxygen.

Analysis of Arterial Blood Gas Data

⑤ ABGs provide an assessment of the patient's acid–base status.[4] Low pH values (less than 7.35) indicate an acidemia, whereas high pH values (more than 7.45) indicate an alkalemia (Fig. 71-3). In a metabolic acidosis, the pH is decreased in association with a decreased serum bicarbonate concentration and a compensatory decrease in $PaCO_2$. In a respiratory acidosis while the pH is decreased, the $PaCO_2$ is elevated. The serum bicarbonate concentration is variable, depending on whether it is an acute disturbance (minimal increase in serum bicarbonate) or a chronic respiratory acidosis (substantial increase in serum bicarbonate). In a metabolic alkalosis, the pH is elevated in association with an increased bicarbonate concentration and a compensatory increase in $PaCO_2$. In a respiratory alkalosis, while the pH is also elevated, the $PaCO_2$ is decreased. As with respiratory acidosis, the metabolic compensation is variable: a minimal decrease in serum bicarbonate is often noted in acute respiratory alkalosis, while a larger decrease in $[HCO_3^-]$ is common with chronic respiratory alkalosis. Although each measurement has a normal range (see Table 71-3), it is often easiest to consider the midpoint of each range as the normal value. This would correlate to a pH of 7.4, $PaCO_2$ of 40 mm Hg (5.3 kPa), and HCO_3^- of 24 mEq/L (mmol/L). Steps in acid–base interpretation, using this physiologic approach, are described in Table 71-4. While beyond the scope of this chapter, two other approaches to assess acid–base status (ie, the physicochemical [Stewart's] approach and the base excess approach) are sometimes used in clinical practice.[5,6]

TABLE 71-4

Steps in Acid–Base Diagnosis

1. Obtain ABG and electrolyte panel simultaneously
2. Compare $[HCO_3^-]$ on ABG and electrolyte panel to verify accuracy
3. Calculate SAG (corrected for albumin when appropriate)
4. Is acidemia (pH <7.35) or alkalemia (pH >7.45) present?
5. Is the primary abnormality respiratory (alteration in $PaCO_2$) or metabolic (alteration in HCO_3^-)?
6. Estimate compensatory response (Table 71-7)
7. Compare change in $[Cl^-]$ with change in $[Na^+]$
8. Compare the relative change of HCO_3^- and SAG to rule out mixed disorder(s)

$[Cl^-]$, chloride ion; $[Na^+]$, sodium ion.

When ABGs differ significantly from those expected on the basis of the patient's clinical condition and previous laboratory determinations, additional venous blood samples should be drawn to assess plasma electrolyte concentrations. The bicarbonate calculated from the patient's $PaCO_2$ and pH of the blood gas should be compared with the measured total CO_2 content (the amount of CO_2 gas extractable from plasma, consisting of HCO_3^-, H_2CO_3, and PCO_2). Ordinarily, the blood gas bicarbonate value is approximately 1 to 2 mEq/L (mmol/L) less than the total CO_2 content.[7] If these values do not correspond, the results should be interpreted with caution because the difference can reflect an error in the blood collection or storage of the sample, or in the calibration of the blood gas analyzer.

METABOLIC ACID–BASE DISORDERS

Metabolic Acidosis

Metabolic acidosis is characterized by a decrease in pH as the result of a primary decrease in serum bicarbonate concentration.

Pathophysiology

Metabolic acidosis can result from the buffering (consumption of HCO_3^-) of an exogenous acid, an organic acid accumulating because of a metabolic disturbance (eg, lactic acid or ketoacids), or the progressive accumulation of endogenous acids secondary to impaired kidney function (eg, phosphates and sulfates).[8] The serum HCO_3^- can also be decreased as the result of a loss of bicarbonate-rich body fluids (eg, diarrhea, biliary drainage, or pancreatic fistula) or occur secondary to the rapid administration of non-alkali–containing IV fluids (dilutional acidosis).[8]

The SAG, as defined below, can be used to determine whether an organic or mineral acidosis is present.

$$SAG=[Na^+]-[Cl^-]-[HCO_3^-]$$

SAG=[Na+]-[Cl-]-[HCO3-]

To maintain electroneutrality, the total concentration of cations in the serum must equal the total concentration of anions.

$$[Na^+]+[UCs]=([Cl^-]+[HCO_3^-])+[UAs]$$

[Na+]+[UCs]=([Cl-]+[HCO3-])+[UAs]

The cation concentration is equal to the sodium concentration plus that of “unmeasured” cations (UCs), predominantly magnesium, calcium, and potassium. The anion concentration is equal to the concentrations of chloride, bicarbonate, and “unmeasured” anions (UAs), including proteins, sulfates, phosphates, and organic anions. Therefore, as the result of the combination of the two equations above, the SAG can be expressed as:

$$SAG=[UAs]-[UCs]$$

SAG=[UAs]-[UCs]

The normal SAG is approximately 10 mEq/L (mmol/L), with a range of 8 to 12 mEq/L (mmol/L). Differences exist in SAG based on clinical laboratories;

therefore, the clinician should identify the normal SAG where practicing.[7] Increases in the anion gap (AG) to values of greater than or equal to 20 mEq/L (mmol/L) are indicative of the accumulation of UAs in ECF. The SAG calculation assumes normal serum albumin. In cases of hypoalbuminemia, the SAG may be underestimated. For every decrease in serum albumin by 1 g/dL (10 g/L) below the normal value of 4.5 g/dL (45 g/L), the SAG is decreased by 2.5 mEq/L (mmol/L).[7]

These UAs are generated as the result of the consumption of HCO_3^- by endogenous organic acids such as lactic acid, acetoacetic acid, or β-hydroxybutyric acid or from the ingestion of toxins such as methanol or ethylene glycol. The degree of elevation in the SAG is dependent on the clearance of the anion, and the multiple factors that influence HCO_3^- concentrations. Thus, the SAG is a relative rather than an absolute indication of the cause of metabolic acidosis. The SAG can also be elevated in metabolic acidosis because of kidney disease, as a result of the accumulation of various organic anions, phosphates, and sulfates.

A delta ratio may be calculated in patients with an elevated SAG to help determine if another acid–base disorder exists. The general rule is that for every 1 mmol of acid present causing a 1 mEq increase in SAG, the serum bicarbonate should drop by 1 mEq leading to a delta gap of 1. A delta ratio equal to 1 indicates an uncomplicated or pure elevated SAG metabolic acidosis. A delta ratio less than 1 indicates a mixed elevated SAG and non-SAG metabolic acidosis. A delta ratio greater than 1 indicates an elevated SAG metabolic acidosis and metabolic alkalosis.[9]

In hyperchloremic metabolic acidosis, bicarbonate losses from the ECF are replaced by chloride, and the SAG remains normal. This decrease in bicarbonate may be due to gastrointestinal (GI) tract losses, dilution of bicarbonate in the ECF as a result of the addition of sodium chloride solutions or chloride-containing acids. Common causes of metabolic acidosis with an increased or a normal SAG are listed in Table 71-5.

TABLE 71-5

Common Causes of Metabolic Acidosis

Increased Serum Anion Gap	Normal Serum Anion Gap/Hyperchloremic States

Ketoacidosis
  Alcoholic
  Diabetic
  Starvation
Kidney disease
  AKI
  CKD
Lactic acidosis (see Table 71-7)
5-Oxyprolinemia (acetaminophen)
Toxins/overdoses
  Ethylene glycol
  Methanol
  Propyl alcohol
  Propylene glycol
  Salicylate
	Acid ingestion/administration (ammonium chloride, hydrochloric acid)
	GI bicarbonate loss
	  Diarrhea, high output ileostomy
	  External pancreatic or small bowel drainage (fistula)
	  Ureteroenterostomy (urinary diversion)
	  Calcium chloride (acidifying agent)
	  Magnesium sulfate (diarrhea)
	  Cholestyramine (bile acid diarrhea)
	Excessive administration of chloride salts (eg., sodium chloride, PN)
	Renal bicarbonate loss
	  Adrenal insufficiency
	  Carbonic anhydrase inhibitors (eg, acetazolamide, topiramate)
	  Hypoaldosteronism
	RTA (see Table 71-6)

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs; PN, parenteral nutrition; RTA, renal tubular acidosis.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis can result from increased GI bicarbonate loss, renal bicarbonate wasting, impaired renal acid excretion, exogenous acid gain, topiramate, or chloride-containing IV fluids.[8] GI disorders such as diarrhea, biliary, or pancreatic drainage through either a surgical drain or fistula can result in the loss of large volumes of bicarbonate-containing fluids. Severe diarrhea, the most common cause of hyperchloremic metabolic acidosis, can lead to significant bicarbonate losses as increased GI motility precludes absorption of bicarbonate in the GI tract. Patients who have undergone ureteral diversion into the sigmoid colon or isolated ileal loop can also develop a hyperchloremic metabolic acidosis. This is the result of a net loss of bicarbonate, given that chloride is reabsorbed, and bicarbonate is secreted by GI epithelial cells in the presence of the urine that is retained in the colon or bowel loop.

Hyperchloremic metabolic acidosis caused by renal bicarbonate wasting is the defining disturbance in proximal or Type II renal tubular acidosis (RTA) and is a complication of therapy with carbonic anhydrase inhibitors, particularly when they are administered for multiple doses.[8] Topiramate, an anticonvulsant that inhibits carbonic anhydrase, has been reported to cause hyperchloremic metabolic acidosis, proximal RTA and nephrolithiasis, particularly when administered at higher doses and for prolonged periods.[10] The metabolic acidosis observed in patients with kidney disease is initially hyperchloremic but can progress to an anion-gap acidosis as kidney disease progresses and sulfates, phosphates, and other anions accumulate.[7] Hyperchloremic metabolic acidosis can also result from the exogenous administration of acid (hydrochloric acid, ammonium chloride) or the unbuffered administration of acid salts from the amino acids in parenteral nutrition.[11]

Renal Tubular Acidosis

⑥ Renal tubular disorders can involve the proximal tubule, with a resultant failure to reabsorb filtered bicarbonate, or affect acid excretion in the distal tubule. The distal RTAs are the most common and are all characterized by impaired net acid excretion. The distal RTAs are subdivided into those that are associated with hypokalemia (type I) and those associated with hyperkalemia (type IV). Type II represents proximal RTA. Type III is extremely rare and will not be discussed. Common causes of RTAs are presented in Table 71-6.

TABLE 71-6

Renal Tubular Acidosis

	Type I	Type II	Type IV
Location	Distal tubules	Proximal tubules	Adrenal/Distal tubules
Primary defect	Impaired urinary H^+ secretion	Decreased urinary HCO_3^- reabsorption	Aldosterone deficiency or resistance
Acidosis	Yes (severe)	Yes	Yes (mild)
UAG	Positive	Negative	Positive
Urine pH	>5.5	<5.5	<5.5
Serum potassium	Low	Low/normal	High
Etiology*	Heredity Autoimmune diseases Primary biliary cirrhosis Rheumatoid arthritis Sjögren syndrome SLE Thyroiditis Hypercalcemia Medications Amphotericin B Cisplatin Ifosfamide Lithium Pentamidine Trimethoprim	Heredity Amyloidosis Fanconi Syndrome Medications Acetazolamide Aminoglycosides Cisplatin Foscarnet Ifosfamide 6-Mercaptopurine Tetracyclines (expired) Topiramate Valproate Multiple myeloma Nephrotic syndrome Sjögren syndrome Toxic metal exposure	Heredity Adrenal insufficiency, primary Autoimmune adrenalitis Adrenal suppression 21-hydroxylase deficiency Adrenal insufficiency, secondary ACEI/ARB/renin inhibitors CKD Diabetes mellitus type 2 Hypertension Hypothalamic-pituitary disease Aldosterone resistance Aldosterone antagonists NSAIDs Potassium sparing diuretics Trimethoprim Chronic interstitial nephropathy (nephritis, obstructive uropathy, HIV nephropathy) General distal tubule defect Sickle cell nephropathy SLE Amyloidosis Renal transplant rejection Chronic cyclosporine toxicity

*Not a comprehensive list, but includes common clinically important disease associations and medications; ACE, angiotensin-converting enzyme; ARB, angiotensin II receptor blocker; CKD, chronic kidney disease; NSAID, nonsteroidal anti-inflammatory drug; SLE, systematic lupus erythematosus.

Data from References 7,12,13.

Patients with classic distal (type I) RTA have impaired hydrogen ion secretion and are unable to excrete the daily acid load necessary to maintain acid–base balance.[12,13] These patients are unable to maximally acidify their urine (ie, attain urine pH less than 5.5), even in the face of an acid challenge. Type I RTA may be the result of a primary tubular defect or develop secondary to a wide variety of medications (eg, amphotericin B, ifosfamide, lithium) and disorders including hypercalcemia, and autoimmune disorders such as systemic lupus erythematosus.[7,12,13] The primary form of this disorder usually occurs in children and can result in severe acidosis, slowed growth, nephrocalcinosis, and kidney stones. In adults, clinical complications include osteomalacia, nephrocalcinosis, and recurrent kidney stones.

Proximal (type II) RTA is characterized by defects in proximal tubular reabsorption of bicarbonate. Normally, 80% to 85% of filtered bicarbonate is reabsorbed in the proximal tubule.[7,14] Defects in proximal tubular bicarbonate reabsorption result in increased delivery of bicarbonate to the distal nephron, which has a limited capacity for bicarbonate reabsorption. As a result, at a normal serum bicarbonate concentration, the filtered bicarbonate load is incompletely reabsorbed, and is lost in the urine. Thus, patients with proximal RTA present with a chronic, nonprogressive hyperchloremic metabolic acidosis. These patients are able to acidify their urine in response to an acid load but develop bicarbonaturia at a reduced serum bicarbonate concentration following bicarbonate loading. The impaired bicarbonate reabsorption results in salt wasting and secondary hyperaldosteronism. Hypokalemia, which can be severe, usually develops as a result of the hyperaldosteronism and bicarbonaturia.[7,14] Proximal RTA usually presents as an acquired disorder, secondary to carbonic anhydrase inhibitor therapy, a variety of diseases (eg, amyloidosis, multiple myeloma, nephrotic syndrome) or exposure to toxins (eg, lead, cadmium, mercury, expired tetracyclines).

The hyperkalemic distal (type IV) RTAs are a heterogeneous group of disorders characterized by hypoaldosteronism or generalized distal tubule defects. The most common form of type IV RTA is hyporeninemic hypoaldosteronism. This syndrome is most commonly associated with diabetic nephropathy, but can also be seen in a variety of other disorders, including chronic interstitial nephritis, sickle-cell disease, human immunodeficiency virus (HIV) nephropathy, and obstructive uropathy.[7,12] The clinical presentation of this syndrome is often exacerbated by medications that can interfere with the renin–angiotensin–aldosterone system, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, renin inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs). Patients with this form of RTA are able to maximally acidify their urine (urine pH less than 5.5). The primary defect in acid excretion is impaired ammoniagenesis caused by decreased kidney function. Treatment to control the hyperkalemia is usually sufficient to reverse the metabolic acidosis, and mineralocorticoid replacement is frequently unnecessary.

Hyperkalemic distal (type IV) RTA resulting from generalized distal tubule defects is less common than hyporeninemic hypoaldosteronism but is more common than classic distal (type I) RTA. Patients with this defect have impaired tubular potassium secretion in addition to impaired urinary acidification (urine pH more than 5.5, despite acidemia or acid loading). Urinary obstruction is the most frequent cause of this disorder, but it can also be associated with sickle-cell nephropathy, systemic lupus erythematosus, HIV nephropathy, analgesic misuse nephropathy, amyloidosis, kidney transplant rejection, and chronic cyclosporine nephrotoxicity.

Elevated Anion Gap Metabolic Acidosis

Metabolic acidosis with an increased SAG commonly results from increased endogenous organic acid production.[15] In lactic acidosis, lactic acid accumulates as a by-product of anaerobic metabolism.[16] Accumulation of the ketoacids β-hydroxybutyric acid and acetoacetic acid defines the ketoacidosis of uncontrolled diabetes mellitus (see Chapter 94, Diabetes Mellitus), alcohol intoxication (see Chapter 55, Portal Hypertension and Cirrhosis, and Chapter 86, Substance Use Disorders II), and starvation (see Chapter e83, Eating Disorders) (Table 71-5).[17] Toxic ingestions of methanol and ethylene glycol are also associated with high anion gap metabolic acidosis and can be differentiated from other causes of SAG by the presence of an elevated osmolar gap. An elevated osmolar gap is considered when the measured serum osmolality is more than 10 mOsm/kg (mmol/kg) greater than the calculated serum osmolality.[7] In advanced kidney disease, accumulation of phosphate, sulfate, and organic anions is responsible for the increased SAG, which is usually less than 24 mEq/L (mmol/L).[2] The severe metabolic acidosis seen in myoglobinuric acute kidney injury (AKI) as a result of rhabdomyolysis may be caused by the metabolism of large amounts of sulfur-containing amino acids released from myoglobin. The mechanisms responsible for the development of acidosis in these settings are diverse.

The presence of mild elevations in the SAG cannot be automatically attributed to the presence of a high SAG metabolic acidosis. Elevations in the SAG are commonly seen in hospitalized patients, especially those who are critically ill.[18] A variety of factors can contribute to this nonspecific elevation in the SAG, including the presence of alkalemia, which increases the anionic charge of albumin and other plasma proteins. The usefulness of the SAG as a marker of acid–base status is dependent on proper interpretation of a patient's clinical status. Despite these limitations, when the SAG is greater than or equal to 20 mEq/L (mmol/L), it is generally considered a high anion gap or a significant organic acidosis.

Lactic Acidosis

Serum lactate levels are often elevated in acutely ill patients and can be used as a marker for severity of illness and response to therapy.[19] Serum lactate levels are considered normal in healthy subjects at approximately 1 mEq/L (mmol/L).[16] Hyperlactatemia is defined as a serum lactate greater than 2 mmol/L with lactic acidosis considered when serum lactate levels are greater than 4 mmol/L with concomitant acidosis.[19] Lactic acid is the end product of anaerobic metabolism of glucose (glycolysis).[13] In normal individuals, lactic acid derived from pyruvate enters the circulation in small amounts and is promptly removed by the liver. In the liver, and to a lesser extent in the kidney, lactic acid is reoxidized to pyruvic acid, which is then metabolized to CO_2 and H_2O.

Classically, lactic acidosis has been differentiated into disorders associated with tissue hypoxia (type A lactic acidosis) and disorders associated with deranged oxidative metabolism (type B lactic acidosis), although the distinction between them is blurred (Table 71-7).[16,19] Metabolic disturbances can result in increased tissue pyruvate production or impaired utilization, with proportional increases in lactate concentrations. Increased lactate production is more commonly associated with alterations in tissue redox state, resulting in preferential conversion of pyruvate to lactate. During anaerobic metabolism, reduced nicotinamide adenine dinucleotide accumulates, driving the conversion of pyruvate to lactate and increasing the lactate-to-pyruvate ratio. States of enhanced metabolic activity (eg, grand mal seizures, strenuous exercise, hyperthermia), decreased tissue oxygen delivery (eg, severe anemia, hypoxia, circulatory shock, carbon monoxide poisoning), or impaired oxygen utilization (eg, cyanide toxicity) are all associated with lactic acidosis. Impaired hepatic clearance of lactate, as seen in hypoperfusion states, liver failure, and alcohol intoxication, can also result in lactic acidosis.

TABLE 71-7

Causes of Lactic Acidosis

Type A (hypoxia)	Type B (metabolic derangement)
Carbon monoxide poisoning Increased oxygen demands Hyperthermia Seizures Shivering Vigorous exercise Regional tissue ischemia Severe anemia Severe hypoxemia Shock Cardiogenic Hemorrhagic Hypovolemic Septic	D-lactic acidosis Diabetes mellitus Inborn errors of metabolism and mitochondrial myopathies Medications/Toxins Alcohols Ethanol Ethylene glycol Methanol Propofol (prolonged, high dose infusions) Propylene glycol (IV formulations of lorazepam, pentobarbital, phenytoin, trimethoprim/sulfamethoxazole) Beta-adrenergic agonists (albuterol, epinephrine) Cyanide (sodium nitroprusside) Entecavir Isoniazid Iron Linezolid Metformin NRTIs (abacavir, lamivudine, stavudine, tenofovir) Ombitasvir, paritaprevir, ritonavir, dasabuvir (Viekira Pak®) Phentermine-topiramate (Qsymia®) Salicylates Telbivudine Theophylline Systemic disease Malignancy Liver failure Thiamine deficiency

Cardiovascular and septic shock, with resultant tissue hypoperfusion, are the most common causes of lactic acidosis.[16] Poor tissue perfusion and hypoxia influence enzymatic pyruvate and lactate metabolism to stimulate anaerobic glycolysis and to decrease lactate utilization. This leads to hyperlactatemia and lactic acidosis. The mortality rate of this type of lactic acidosis can be 50% or greater and correlates with the degree of hyperlactatemia.[20]

Lactic acidosis associated with liver disease, toxins, and congenital enzyme deficiency can be caused by deranged oxidative metabolism or impaired lactate clearance.[19] The exact role of diabetes mellitus in the induction of lactic acidosis is not clear. It may involve a decrease in pyruvate dehydrogenase activity, the enzyme responsible for pyruvate metabolism. Lactic acidosis in neoplastic disease is uncommon and reported mostly in patients with myeloproliferative disorders. Leukocytes and neoplastic cells in general have high rates of glycolysis. In the case of a large tumor or tightly packed bone marrow, oxygenation can be decreased, favoring the accumulation of lactate. Lactic acidosis has been reported in patients with massive liver tumors, and it has been postulated that the liver uptake of lactate is decreased in these patients. Lactic acidosis associated with seizures is usually transient and occurs because of excessive muscle activity.[16,19]

A number of medications have been associated with the development of lactic acidosis. Metformin (0.03 cases per 1,000 person-years) remains the most common medication associated with lactic acidosis.[21] The primary suspected mechanism for metformin-induced lactic acidosis is inhibition of liver gluconeogenesis as the result of its inhibitory effects on pyruvate carboxylase, which is necessary for the conversion of pyruvate to glucose. Other possible pathways for metformin-associated lactic acidosis include a decrease in both hepatic intracellular pH and cardiac output, an increase in lactate production in the gut, and increased renal loss of bicarbonate. Risk factors for metformin-induced lactic acidosis include impaired kidney function, liver disease, dehydration, advanced age, excessive alcohol use, concomitant carbonic anhydrase inhibitor use, and supratherapeutic dosing.[19,22] Metformin should be discontinued during periods of tissue hypoxia (eg, myocardial infarction, sepsis), at the time of or before iodinated contrast imaging procedures in patients with eGFR 30 to 60 mL/min/1.73 m^2, withheld on the day of surgery and during periods of restricted food intake.[23,24] Metformin should only be reinstituted when the patient's kidney function is stable, and the patient is tolerating adequate oral diet.

The older nucleoside-analog reverse transcriptase inhibitors (NRTIs), particularly stavudine, have been associated with lactic acidosis (3.9 cases per 1,000 person-years) in patients with hepatic steatosis.[25] The proposed mechanism of NRTI-induced lactic acidosis is the inhibition of the enzyme DNA polymerase gamma that is responsible for mitochondrial DNA synthesis.[26] Lactic acidosis has been rarely reported with tenofovir, lamivudine, abacavir, and entecavir.

Linezolid impairs mitochondrial function and has been rarely reported to cause lactic acidosis, usually after prolonged (more than or equal to 4 weeks) therapy.[27] The weight loss combination medication phentermine-topiramate (Qsymia®) has been reported to cause lactic acidosis.[28] Use of the Viekira Pak® (ombitasvir, paritaprevir, ritonavir, dasabuvir) may cause lactic acidosis in patients without severe liver dysfunction when used to treat hepatitis C.[29]

Propylene glycol is commonly used as a solubilizing agent in IV medications (eg, lorazepam, pentobarbital, phenytoin, trimethoprim/sulfamethoxazole) and is predominantly metabolized to lactic acid via the hepatic enzyme alcohol dehydrogenase.[30–32] The administration of large doses of propylene glycol, particularly to patients with impaired kidney or liver function, can lead to a lactic acidosis with an osmolar gap. Thus, serial measurement of the osmolar gap can be used to detect propylene glycol accumulation.[30,31]

The association between propofol and lactic acidosis was initially described in children.[33] This association is now recognized in adults and has come to be known as the propofol-related infusion syndrome. In addition to lactic acidosis, cardiac failure, rhabdomyolysis, and AKI have been observed primarily because of uncoupling of oxidative phosphorylation and impaired oxidation of free fatty acids. To minimize the risk of propofol infusion syndrome, it is recommended not to exceed 4 mg/kg/hour for more than 48 hours unless the perceived benefit exceeds the risk.[33]

Clinical Presentation

Chronic metabolic acidosis is usually not associated with severe acidemia and is relatively asymptomatic. The major manifestations are bone demineralization with growth failure and short stature in children and both osteomalacia and osteopenia in adults.[6,28] Chronic metabolic acidosis is also associated with nonspecific symptoms including anorexia, nausea, weight loss, and muscle weakness.

Severe metabolic acidosis is usually associated with acute processes. The manifestations of severe acidemia (pH less than 7.20) involve the cardiovascular, respiratory, and central nervous system (CNS). Hyperventilation is often the first sign of metabolic acidosis. At a pH of 7.2, pulmonary ventilation increases approximately fourfold, and an eightfold increase has been noted at a pH of 7.[34,35] Respiratory compensation can occur as Kussmaul respirations—the deep, rapid respirations seen commonly in patients with diabetic ketoacidosis. In extremely severe acidosis (pH less than 6.8), CNS function is disrupted to such a degree that the respiratory center is depressed.

CNS depression correlates more closely with spinal fluid pH than with blood pH. For this reason, neurologic symptoms tend to occur more frequently and to a greater degree in patients with respiratory acidosis because the CO_2 accumulated in the respiratory form readily crosses the blood–brain barrier to cause acidosis in the CNS.[4] Because of the slow penetration of administered bicarbonate into the CNS, the CNS pH fails to normalize as rapidly as blood pH. Therefore, patients continue to hyperventilate because of sustained CNS acidity, and severe respiratory alkalosis can occur. Sustained lowering of the $PaCO_2$ within 12 to 36 hours is to be anticipated during the correction of any metabolic acidosis.[4]

Systemic acidosis can cause peripheral arteriolar dilatation, characterized by flushing, a rapid HR, and wide pulse pressure. Initially, cardiac output can be increased, but as acidosis becomes more severe, myocardial contractility becomes impaired, and cardiac output decreases. The effects of vagal stimulation are also enhanced at reduced pH levels, likely a consequence of inhibition of acetylcholinesterase. This increases the danger of vagally mediated bradycardia and heart block during acidosis.[36]

GI symptoms of metabolic acidosis include loss of appetite, nausea, and vomiting. Severe acidosis (pH less than 7.1) interferes with carbohydrate metabolism and insulin utilization, and results in hyperglycemia. Metabolic acidosis alters potassium homeostasis and contributes to the development of hyperkalemia. The magnitude of the effect on serum potassium depends on the type of acidosis: Acidosis caused by mineral acids (eg, hydrochloric acid) is associated with a greater change in potassium levels than acidosis caused by organic acids (eg, lactic acidosis), in which the increase in potassium attributable to the acidosis is minimal.[37]

Compensation

The patient's primary means to compensate for metabolic acidosis is to increase carbon dioxide excretion by increasing the RR. This results in a decrease in $PaCO_2$. This ventilatory compensation results from stimulation of the respiratory center by changes in cerebral bicarbonate concentration and pH.[4,38] For every 1 mEq/L (mmol/L) decrease in bicarbonate concentration below the average of 24, the $PaCO_2$ decreases by approximately 1 to 1.5 mm Hg (0.13-0.20 kPa) from the normal value of 40 mm Hg (5.3 kPa). General guidelines for the assessment and interpretation of acid–base disorders based on observed compensatory responses are presented in Table 71-8.[7]

TABLE 71-8

Guidelines for Interpretation of Acid–Base Disorders Based on Compensatory Responses

Acidosis	**Compensation**
Metabolic	$PaCO_2$ (in mm Hg) should decrease by 1.25 times the fall in plasma $[HCO_3^-]$ (in mEq/L or mmol/L)
Acute respiratory	Plasma $[HCO_3^-]$ should increase by 0.1 times the increase in $PaCO_2$ (in mm Hg)
Chronic respiratory	Plasma $[HCO_3^-]$ should increase by 0.4 times the increase in $PaCO_2$ (in mm Hg)
Alkalosis	**Compensation**
Metabolic	$PaCO_2$ (in mm Hg) should increase by 0.6 times the rise in plasma $[HCO_3^-]$ (in mEq/L or mmol/L)
Acute respiratory	Plasma $[HCO_3^-]$ should decrease by 0.2 times the decrease in $PaCO_2$ (in mm Hg), but usually not to <18 mEq/L (mmol/L)
Chronic respiratory	Plasma $[HCO_3^-]$ should fall by 0.4 times the decrease in $PaCO_2$ (in mm Hg), but usually not to <14 mEq/L (mmol/L)

HCO_3^-, bicarbonate; $PaCO_2$, partial pressure of carbon dioxide from arterial blood; multiply values expressed in kPa by 7.519 to convert to mm Hg.

Data from Reference 7.

The anticipated $PaCO_2$ associated with a given bicarbonate concentration for patients with uncomplicated metabolic acidosis can also be calculated using the Winters' formula:[7]

$$PaCO_2 = (1.5 \times [HCO_3^-] + 8) \pm 2 \text{ for } PaCO_2 \text{ in mm Hg}$$
PaCO2=(1.5×[HCO3-]+8)±2 for PaCO2 in mm Hg

$$(PaCO_2 = (0.2 \times [HCO_3^-] + 1.1) \pm 0.3 \text{ for } PaCO_2 \text{ in kPa})$$
(PaCO2=(0.2×[HCO3-]+1.1)±0.3 for PaCO2 in kPa)

For example, 95% of patients with a plasma bicarbonate of 16 mEq/L (mmol/L) should have an arterial PCO_2 of 30 to 34 mm Hg (4.0-4.5 kPa). An observed arterial PCO_2 within this range is consistent with physiologic respiratory compensation for a metabolic acidosis and suggests that there is no respiratory disturbance. In contrast, if the PCO_2 is less than 30 mm Hg (4.0 kPa), a superimposed respiratory alkalosis can be present, whereas if the PCO_2 is greater than 34 mm Hg (4.5 kPa), a superimposed respiratory acidosis is likely present.

CLINICAL PRESENTATION: Metabolic Acidosis

General

- The patient usually is relatively asymptomatic if the acidosis is acute and mild. In those with severe acidemia (pH less than 7.20), the cardiovascular, respiratory, and CNS systems can be affected.

Symptoms

- The patient may complain of loss of appetite, nausea, and vomiting.

Signs

- Cardiac: Flushing, a rapid HR, wide pulse pressure, and an increase in cardiac output can be seen initially. This can be followed by a reduction in cardiac output, BP, and liver and kidney blood flow.
- Cerebral: Obtundation or coma.
- Metabolic: Insulin resistance; increased protein degradation; increased metabolic demands.
- GI: Nausea, vomiting, loss of appetite.
- Respiratory: Dyspnea, hyperventilation with deep, rapid respirations is seen in those with severe acidosis.
- Chronic acidemia causes bone demineralization with the development of growth failure and short stature in children and osteomalacia and osteopenia in adults.

Laboratory Tests

- Serum CO_2 is low. Hyperglycemia and hyperkalemia are common. Patients with a pH of less than 7.2 are deemed to have a severe acidosis.

TREATMENT OF METABOLIC ACIDOSIS

⑦ Asymptomatic patients with mild to moderate degrees of acidemia (plasma bicarbonate of 12-20 mEq/L [mmol/L]; pH 7.2-7.4) do not require emergent therapy. They can usually be managed with gradual correction of the acidemia, over a period of days to weeks, using oral sodium bicarbonate or other alkali preparations (Table 71-9). In all forms of chronic metabolic acidosis, primary therapy should be directed at treating the underlying disease state. GI pathology should be treated to reduce ongoing bicarbonate losses, and factors that exacerbate RTA should be treated. If acidemia persists, alkali therapy should be instituted with the goal of normalization of blood pH. The loading dose (LD) of alkali to initially correct the acidemia can be calculated as follows:

$$\text{LD(mEq or mmol/L)}=(V_D\times \text{BW})\times(\text{desired}[HCO_3^-]\text{-current }[HCO_3^-])$$

LD(mEq or mmol/L)=(VD×BW)×(desired[HCO3-]-current [HCO3-])

TABLE 71-9

Therapeutic Alternatives for Oral Alkali Replacement

Product	Milliequivalents of Alkali	Dosage Form(s)
Sodium citrate/citric acid	1 mL contains 1 mEq sodium and is equivalent to 1 mEq bicarbonate	Solution, sodium citrate 500 mg, citric acid 334 mg per 5 mL
Sodium bicarbonate	3.9 mEq bicarbonate per tablet (325 mg) 7.8 mEq bicarbonate per tablet (650 mg) 60 mEq bicarbonate per teaspoon (5 g per teaspoon)	Tablet, 325 mg Tablet, 650 mg Baking soda powder
Potassium citrate	Each tablet contains 5, 10, or 15 mEq potassium and delivers approximately 5, 10, or 15 mEq bicarbonate	Tablet Extended Release, 5 mEq Tablet Extended Release, 10 mEq Tablet Extended Release, 15 mEq
Potassium bicarbonate/potassium citrate	Each tablet contains 10, 20, or 25 mEq potassium and delivers approximately 10, 20 or 25 mEq bicarbonate	Tablet Effervescent, 10 mEq Tablet Effervescent, 20 mEq Tablet Effervescent, 25 mEq
Potassium citrate/citric acid	Each packet contains 30 mEq potassium and delivers approximately 30 mEq bicarbonate Each mL contains 2 mEq potassium and delivers approximately 2 mEq bicarbonate	Powder for solution, potassium citrate monohydrate 3300 mg, citric acid monohydrate 1002 mg per packet Solution, potassium citrate monohydrate 1100 mg, citric acid monohydrate 334 mg per 5 mL
Sodium citrate/potassium citrate/citric acid	1 mL contains 1 mEq potassium and 1 mEq sodium ion, and delivers approximately 2 mEq bicarbonate	Solution, citric acid 334 mg, sodium citrate 500 mg, and potassium citrate 550 mg per 5 mL

where V_D is the volume of distribution of bicarbonate (0.5 L/kg) and BW is body weight in kg.[8,39]

Thus, for a 60-kg patient with a serum bicarbonate of 15 mEq/L (mmol/L), the LD is calculated:

$$\begin{aligned} \text{LD(mEq)} &= (0.5\ \text{L/kg} \times 60\ \text{kg}) \times (24\ \text{mEq/L} - 15\ \text{mEqL}) \\ \text{LD} &= 30\ \text{L} \times 9\ \text{mEq/L} \\ \text{LD} &= 270\ \text{mEq} \end{aligned}$$

LD(mEq)=(0.5 L/kg×60 kg)×(24 mEq/L-15 mEqL)LD=30 L×9 mEq/LLD=270 mEq

The calculated LD of alkali should be administered over several days to avoid volume overload from the accompanying sodium load. For this scenario, a regimen of 60 to 70 mEq (mmol) three times a day for 3 to 5 days should result in an increase in HCO_3^- levels toward normal. In addition to the calculated LD, supplemental alkali must also be provided to replace ongoing losses, which can be approximated to be 2 mEq/kg (mmol/kg) per day or 40 mEq (mmol) three times a day. In patients with associated volume depletion, bicarbonate replacement can be provided simultaneous with volume resuscitation by substituting bicarbonate for chloride in IV crystalloid solutions.

In patients with chronic metabolic acidosis because of GI bicarbonate losses, maintenance therapy should provide enough alkali to replace ongoing bicarbonate losses. The magnitude of this replacement is variable and can be substantial (more than 10 mEq/kg [mmol/kg] per day). In addition, associated losses of other electrolytes, such as potassium and magnesium, may need to be replaced (see Chapter 70, Potassium and Magnesium Homeostasis).

Proximal (type II) RTA is a bicarbonate-wasting disorder that requires the administration of large maintenance doses of alkali (10-15 mEq/kg [mmol/kg] per day). As alkali replacement raises the serum bicarbonate concentration toward normal, the proximal tubule's capacity to reabsorb bicarbonate is overwhelmed, and renal bicarbonate wasting increases. In children, aggressive therapy of proximal RTA is necessary to avoid growth retardation and osteopenia. Because this is generally a mild, nonprogressive acidosis in adults, the benefit of alkali therapy is frequently outweighed by the risks of increased potassium wasting. In patients with classic distal (type I) RTA, maintenance therapy usually requires only enough alkali to buffer the amount of acid generated from dietary intake and metabolism. This usually approximates 1 to 3 mEq/kg/day (mmol/kg/day).

⑧ After initial potassium deficits are replaced, ongoing potassium supplementation may not be required, as renal potassium losses decrease following initiation of appropriate alkali therapy. The use of potassium alkali salts can, however, be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyporeninemic-hypoaldosteronism that is often seen in patients with diabetes mellitus can be corrected by the treatment of hyperkalemia alone (see Chapter 70). The use of supplemental alkali (1-2 mEq/kg [mmol/kg] per day) to increase sodium intake and stimulate distal tubular potassium secretion can be beneficial. Some patients may require the administration of pharmacologic amounts of fludrocortisone.[8] Type IV RTA resulting from a generalized distal tubular disorder often responds to low doses of alkali (1.5-2.0 mEq/kg [mmol/kg] per day).[12,14] Corrections of the acidosis along with modest dietary potassium restriction (to 1 mEq/kg [mmol/kg] per day) will often result in the maintenance of serum potassium concentrations of 5 mEq/L (mmol/L) or less.

Veverimer

Veverimer is an investigational medication designed to be used in the treatment of metabolic acidosis of chronic kidney disease (CKD). It is a non-absorbable polymer designed to bind hydrogen chloride in the GI tract with subsequent removal in the feces.[40] Every hydrogen ion bound results in HCO_3^- entering the blood, thus producing an increase in serum HCO_3^- without administering sodium, a mechanism thought to be potentially useful in sodium retentive patients.[41] No changes in fluid or serum concentrations of sodium, potassium, calcium, magnesium, and phosphate have been observed in patients treated with veverimer.[41,42] Adverse medication reactions are primarily GI including nontreatment limiting diarrhea (most common), flatulence, nausea, and constipation.[42] Administration is orally as a suspension in water. Dosing has not been fully elucidated but the Phase 3, 40-week study used a dose of 6 grams daily.[42] Veverimer has not yet been approved by the FDA.

Acute Severe Metabolic Acidosis

⑨ The management of life-threatening acute metabolic acidosis (plasma bicarbonate of 8 mEq/L [mmol/L] and pH less than 7.20) is dependent on the underlying cause and the patient's cardiovascular status. In some cases, patients will require emergent hemodialysis therapy (see Chapter 64). Patients with hyperchloremic acidosis (eg, diarrhea-induced) are unable to regenerate bicarbonate, and the generation of new bicarbonate by the kidneys can require several days before one can observe a meaningful change in their status. Thus, IV alkali therapy is often required for these patients.

Although conventional wisdom recommends the use of alkali replacement in patients with severe acidemia, studies have not demonstrated that its administration improves patient outcomes.[16,39,43] Alkali therapies may either improve or worsen clinically relevant endpoints such as $[H^+]$, $PaCO_2$, lactate concentrations, and cardiac output. The specific patient populations most likely to benefit or be harmed from alkalinizing therapy are presented in Table 71-10.

TABLE 71-10

Patient Populations Likely to Benefit or Suffer from Alkalinizing Therapy

Patients with Potential for Benefit	Patients with Potential for Harm
Distal (type I) renal tubular acidosis	Hypernatremia
Severe hyperchloremic metabolic acidosis secondary to diarrhea or surgical diversion	Hypervolemia
Specific poisonings and intoxications (eg, salicylate overdose with metabolic acidosis)	AKI
	Chronic heart failure
	Pulmonary disease resulting in decreased ventilation
	Acute lung injury where a lung protective ventilation strategy is used
	Diabetic ketoacidosis

There are several therapeutic alternatives available for the acute correction of severe metabolic acidosis. Sodium acetate, sodium citrate, and sodium lactate are unreliable sources of alkali because their alkalinizing effect is dependent on their oxidative conversion to bicarbonate by the liver. This process is often impaired in critically ill patients, especially those with hepatic disease or circulatory failure. Although sodium bicarbonate is the most widely used IV alkalotic agent, it is frequently ineffective and can actually be deleterious, especially in patients with lactic acidosis.[16,39,44] Among the two remaining alternatives, dichloroacetate (DCA) is investigational and not available in most clinical settings. Tromethamine, or THAM, is a carbon dioxide–consuming, commercially available solution that buffers respiratory as well as metabolic acids but was discontinued by its sole US manufacturer in 2016.

Sodium Bicarbonate

While sodium bicarbonate administration provides fluid and electrolyte replacement and increases arterial pH, it does not improve cardiac function, organ perfusion, or intracellular pH.[17,39,44,45] In patients with AKI, sodium bicarbonate may reduce mortality at 28 days.[43] However, additional research is required to further evaluate the role of sodium bicarbonate in patients with severe metabolic acidemia and AKI given the potential role of renal replacement therapy in this setting. In addition, sodium bicarbonate administration can have paradoxical adverse effects on intracellular pH. When bicarbonate is given by IV infusion, the carbon dioxide generated diffuses more readily than bicarbonate across cell membranes and into cerebrospinal fluid. Therefore, the intracellular pH can be decreased by administration of bicarbonate.[8,43]

Excessive sodium bicarbonate administration can result in (a) a shift of the oxyhemoglobin saturation curve to the left, thereby impairing oxygen release from hemoglobin to tissues; (b) sodium and water overload, with subsequent pulmonary congestion and hypernatremia; (c) paradoxical tissue acidosis as a result of the production of CO_2 that freely diffuses into myocardial and cerebral cells; and (d) decreased ionized calcium with a resultant decrease in myocardial contractility.[8,39] If there is an endogenous source of bicarbonate, such as can occur in the case of ketoacidosis or lactic acidosis, a bicarbonate "overshoot" can develop because the ketoacids (acetoacetic acid and β-hydroxybutyric acid) or lactic acid are converted in the liver to bicarbonate once the underlying cause of acidosis is corrected. Alkalosis can also result if too much sodium bicarbonate is administered too quickly.[8,39]

If IV sodium bicarbonate is used, one must be mindful that the goals are to increase, not normalize, pH (to approximately 7.2) and plasma bicarbonate (to 8-10 mEq/L [mmol/L]). There is no calculative method that will assure attainment of these goals with a given dose of sodium bicarbonate because of the multiplicity of competing processes that can affect acid–base status (eg, vomiting, potential increases in endogenous acid production, and kidney disease) and the marked variability in the volume of distribution of bicarbonate (50% of BW in patients with mild acidosis to approximately 100% in those with severe acidosis).[8,46] The dose of sodium bicarbonate may be calculated using a distribution volume of 50% of BW for all patients to avoid overtreatment.[8] The total dose calculated as described previously in the RTA section should be administered as an infusion over one-half to several hours. Follow-up monitoring of ABGs, beginning no sooner than 30 minutes after the end of the infusion, should be used to guide further therapeutic decisions.[46]

Bicarbonate therapy is generally not necessary for patients with cardiac arrest, even if the initial arrest was unmonitored. The American Heart Association Advanced Cardiac Life Support (ACLS) guidelines state the routine use of sodium bicarbonate is not recommended for patients in cardiac arrest, but may be useful in patients with life-threatening hyperkalemia.[47] The initial dose of sodium bicarbonate in this situation is (1 mEq/kg [mmol/kg]) administered by rapid, direct IV injection.[47] Subsequent doses of sodium bicarbonate should be based on measurements of arterial blood pH and $PaCO_2$ given the propensity for it to cause alkalemia.[46]

Tromethamine

THAM, no longer available in the United States, is a highly alkaline, sodium-free organic amine that acts as a proton acceptor to prevent or correct acidosis.[8,48] THAM combines with hydrogen ions from carbonic acid to form bicarbonate and a cationic buffer, and also acts as an osmotic diuretic to increase urine flow, urine pH, and the excretion of fixed acids, CO_2, and electrolytes.[7,48] It should be administered via a central line and used with extreme caution in patients with severe liver or kidney failure.

Dichloroacetate

DCA, another investigational agent, facilitates aerobic lactate metabolism by stimulating the activity of lactate dehydrogenase, thus reversing hyperlactatemia and elevating blood pH.[49–51] DCA does not improve hemodynamic parameters or clinical outcomes compared to conventional management.[49–51] DCA can cause mild drowsiness and peripheral neuropathy that is reversible upon discontinuation.[51] The future role of DCA in the management of metabolic acidosis, particularly lactic acidosis, remains to be clarified.[16]

Metabolic Alkalosis

Pathophysiology

Metabolic alkalosis is a simple acid–base disorder that presents as alkalemia (increased arterial pH) with an increase in plasma bicarbonate. Metabolic alkalosis is predominantly maintained because of an abnormality in kidney function and does not occur nor cannot be corrected in a matter of hours. Normally, the kidneys are capable of excreting all of the excess bicarbonate presented to them, even during periods of increased bicarbonate loads.[2] As the serum bicarbonate concentration increases, the filtered bicarbonate load exceeds the maximal rate for bicarbonate reabsorption, and the excess bicarbonate is excreted in the urine. Thus, evaluation of patients with metabolic alkalosis must consider two separate issues: (a) the initial process that generates the metabolic alkalosis; and (b) alterations in kidney function that maintain the alkalemia state.[52]

⑩ The generation of metabolic alkalosis can result from reduced renal bicarbonate excretion, excessive losses of hydrogen ions from the kidneys or stomach, or from a gain secondary to the ingestion or administration of bicarbonate-rich fluids.[52,53] In general, these mechanisms can be divided into volume-mediated processes (sodium chloride–responsive), volume-independent processes (sodium chloride–resistant), or not classified by either (Table 71-11).[7,53] Patients with a sodium chloride–responsive metabolic alkalosis will have a urinary chloride concentration less than 10 mEq/L (mmol/L) and patients with a sodium chloride–resistant alkalosis will have a urinary chloride concentration greater than 20 mEq/L (mmol/L).[7]

TABLE 71-11

Causes of Metabolic Alkalosis

Sodium chloride–responsive (urinary chloride concentration <10 mEq/L [mmol/L])
- GI disorders
  - Vomiting
  - Gastric drainage
  - Villous adenoma of the colon
  - Chloride diarrhea
- Diuretic therapy (distant)
- Correction of chronic hypercapnia
- Cystic fibrosis
- Excessive bicarbonate therapy of an organic acidosis
- Mild/moderate potassium deficiency

Sodium chloride–resistant (urinary chloride concentration >20 mEq/L [mmol/L])
- Excess mineralocorticoid activity
  - Hyperaldosteronism
  - Cushing syndrome
  - Bartter syndrome (sodium transport defect in loop of Henle)
  - Gitelman syndrome (sodium transport defect in collecting duct)
- Excessive black licorice intake
- Profound potassium depletion
- Magnesium deficiency
- Liddle syndrome (enhanced sodium reabsorption in collecting duct)
- Diuretic therapy (recent)
- Estrogen therapy

Unclassified
- Alkali administration
- Milk-alkali syndrome
- Massive blood or plasma protein fraction transfusion
- Nonparathyroid hypercalcemia
- Carbohydrate refeeding after starvation

Large doses of penicillin

Sodium Chloride Responsive

⑪ Gastric juice, rich in chloride and hydrogen ions, is secreted at a rate of less than 50 mL/hr in the basal state, but can increase up to fivefold with stimulation. In the gastric parietal cells, the hydrogen ion and bicarbonate are generated from CO_2 and water.[1] The hydrogen ion is secreted into gastric fluid, and the bicarbonate is retained in the ECF. Normally, an amount of bicarbonate equal to the bicarbonate generated in the stomach is eliminated in the alkaline pancreatic and small-bowel secretions, maintaining hydrogen ion balance. With vomiting and nasogastric suctioning, the hydrogen ion is lost externally and metabolic alkalosis results. Diarrhea, as seen with secretory villous adenomas and other secretory diarrheas, often results in excessive GI losses of chloride-rich, bicarbonate-poor fluid, and thus leads to the generation of metabolic alkalosis.

⑫ Diuretic agents acting on the thick ascending limb of the loop of Henle (eg, furosemide, bumetanide, and torsemide) and distal convoluted tubule (eg, thiazides) have most commonly been associated with the generation of metabolic alkalosis.[1,54] These agents promote the excretion of sodium and potassium almost exclusively in association with chloride, without a proportionate increase in bicarbonate excretion. Collecting duct hydrogen ion secretion is stimulated directly by the increased luminal flow rate and sodium delivery, and indirectly by intravascular volume contraction, which results in secondary hyperaldosteronism. Renal ammoniagenesis can also be stimulated by concomitant hypokalemia, further augmenting net acid excretion.

Sodium Chloride Resistant

Mineralocorticoid excess plays a significant role in the maintenance of metabolic alkalosis given that it stimulates collecting duct hydrogen ion secretion. Elevated mineralocorticoid levels directly stimulate collecting duct hydrogen ion secretion, indirectly increase ammoniagenesis by causing hypokalemia, and is associated with both acute and chronic causes including profound potassium deficiency, magnesium deficiency, and estrogen therapy.[1,7,54]

Unclassified

Metabolic alkalosis can also be generated by the gain of exogenous alkali. This is a result of bicarbonate administration or from the infusion of organic anions that are metabolized to bicarbonate, such as acetate, lactate, and citrate. The milk-alkali syndrome was historically a common cause of metabolic alkalosis in patients with peptic ulcer disease secondary to the ingestion of large quantities of milk products and antacids. Administration of high doses of penicillins (eg, ticarcillin) can produce metabolic alkalosis because they act as nonreabsorbable anions, which enhances the secretion of potassium and hydrogen ions and results in hypokalemia and metabolic alkalosis.[55]

Clinical Presentation

There are no unique signs or symptoms associated with mild-to-moderate metabolic alkalosis, but patients may complain of symptoms related to the underlying cause of the disorder (eg, muscle weakness with hypokalemia or postural dizziness with volume depletion).[52,56] They may have a history of vomiting, gastric drainage, or diuretic use, all of which contribute to the development of metabolic alkalosis. Severe alkalemia (blood pH greater than 7.55) has been associated with cardiac arrhythmias, particularly in patients with heart disease, hyperventilation, and hypoxemia.[56] Neuromuscular irritability can be present, with signs of tetany or hyperactive reflexes, possibly caused by the decreased ionized calcium concentration that occurs secondary to the increase in pH. This decrease in ionized calcium may be caused by a conformational change in the albumin molecules to which the calcium is bound, resulting in increased binding, or by decreased competition from hydrogen ions for binding sites on the albumin molecule. Mental confusion, muscle cramping, and paresthesia can also occur.[52] Lastly, patients will be more difficult to liberate from mechanical ventilation.

Compensation

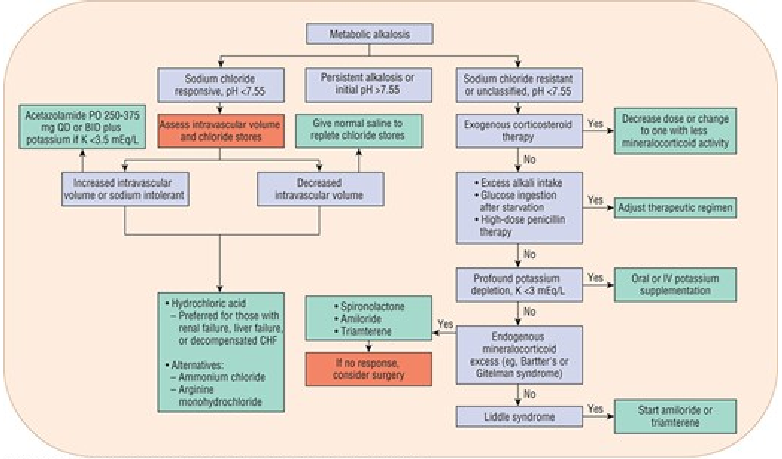
The respiratory response to metabolic alkalosis is hypoventilation, which results in an increased $PaCO_2$. Respiratory compensation is initiated within hours when the central and peripheral chemoreceptors sense an increase in pH. The $PaCO_2$ increases 6 to 7 mm Hg (0.8-0.9 kPa) for each 10 mEq/L (mmol/L) increase in bicarbonate, up to a $PaCO_2$ of approximately 50 to 60 mm Hg (6.7-8.0 kPa) (see Table 71-8) before hypoxia sensors react to prevent further hypoventilation.[7] If the $PaCO_2$ is normal or less than normal, one should consider the presence of a superimposed respiratory alkalosis, which can be secondary to fever, gram-negative sepsis, or pain.

TREATMENT OF METABOLIC ALKALOSIS

Treatment of metabolic alkalosis should be aimed at correcting the factor(s) responsible for the maintenance of the alkalosis.[56] For example, vomiting should be treated with antiemetics; gastric losses of hydrogen ions during nasogastric suction can be modulated by giving histamine blockers such as famotidine or proton pump inhibitors such as omeprazole, and reducing or discontinuing diuretic therapy.[56,57] Metabolic alkalosis will persist until the renal mechanism responsible for maintaining the disorder is corrected, despite the fact that the original cause of the elevated plasma bicarbonate may have resolved. For example, hypovolemia should be treated with sodium chloride to allow excretion of bicarbonate by the kidney. However, patients with severely compromised cardiovascular function may not be able to tolerate this therapeutic approach. In situations such as this and/or the presence of life-threatening alkalosis, a reduction in pH by controlled hypoventilation sometimes using inspired CO_2 with supplemental oxygen to prevent hypoxia has been used. Dialysis using a low bicarbonate dialysate is also indicated in such patients.[7,58] Therapy for metabolic alkalosis can be conceptualized on the basis of the sodium chloride responsiveness of the disorders (Fig. 71-4).

FIGURE 71-4

Treatment algorithm for patients with primary metabolic alkalosis. (BID, twice daily; CHF, chronic heart failure; K, potassium [serum potassium in mEq/L is numerically equivalent to mmol/L]; PO, orally; QD, every day.)



Metabolic alkalosis
Sodium chloride responsive, pH <7.55
Persistent alkalosis or initial pH >7.55
Sodium chloride resistant or unclassified, pH <7.55
Acetazolamide PO 250-375 mg QD or BID plus potassium if K <3.5 mEq/L
Assess intravascular volume and chloride stores
Give normal saline to replete chloride stores
Exogenous corticosteroid therapy
Yes
Decrease dose or change to one with less mineralocorticoid activity
No
Increased intravascular volume or sodium intolerant
Decreased intravascular volume
• Excess alkali intake
• Glucose ingestion after starvation
• High-dose penicillin therapy
Yes
Adjust therapeutic regimen
No
Profound potassium depletion, K <3 mEq/L
Yes
Oral or IV potassium supplementation
No
• Hydrochloric acid
– Preferred for those with renal failure, liver failure, or decompensated CHF
• Alternatives:
– Ammonium chloride
– Arginine monohydrochloride
• Spironolactone
• Amiloride
• Triamterene
Yes
If no response, consider surgery
Endogenous mineralocorticoid excess (eg, Bartter's or Gitelman syndrome)
No
Liddle syndrome
Yes
Start amiloride or triamterene

Sodium Chloride–Responsive Metabolic Alkalosis

Sodium chloride–responsive disorders usually result from volume depletion and chloride loss, which can accompany severe vomiting, prolonged nasogastric suction, and diuretic therapy. Initially, therapy is directed at expanding intravascular volume and replenishing chloride stores. Sodium chloride– and potassium chloride–containing solutions should be administered to patients who can tolerate the volume load.[52] Patients with metabolic alkalosis who are volume overloaded or intolerant to volume administration because of chronic heart failure can benefit from the carbonic anhydrase inhibitor acetazolamide. This agent inhibits the action of carbonic anhydrase, thereby inhibiting renal bicarbonate reabsorption. Unfortunately, it also increases the renal losses of potassium and phosphate. Administration of acetazolamide (250-375 mg once or twice daily) can promote a sufficient bicarbonate diuresis and return the pH toward normal.[52,59] Among mechanically ventilated chronic obstructive pulmonary disease patients having metabolic alkalosis, administration of acetazolamide 500 to 1000 mg twice daily (initiated within 48 hours of ICU admission and continued to ICU discharge) appears to reduce the degree of alkalosis while not affecting duration of mechanical ventilation or any other clinically relevant outcome.[60]

Hemodialysis using a low-bicarbonate dialysate can be used for the rapid correction of severe (pH greater than 7.55) metabolic alkalosis.[7,58] Acidifying agents including hydrochloric acid, ammonium chloride, and arginine monohydrochloride can also be used in such situations; however, availability limits their use as first line.[61,62] In general, this management is reserved for patients who are unresponsive to conventional fluid and electrolyte management or who are unable to tolerate the requisite volume load because of decompensated heart failure or advanced kidney disease.[58]

Hydrochloric Acid

Hydrochloric acid is usually infused IV via a large central vein as a 0.1 to 0.25 N HCl solution in either 5% dextrose or normal saline, although sterile water has also been used. Extemporaneously prepared solutions can be made by adding 100 to 250 mEq (mmol) of HCl through a 0.22-mm filter into a glass container of saline or dextrose. The rate of infusion should be 100 to 125 mL/hr (10-25 mEq/h [mmol/h]). A severe transient respiratory acidosis can occur if the hydrochloric acid is infused too quickly because of a slower reduction of the elevated bicarbonate concentration in the cerebrospinal fluid than in the ECF. Improvement is usually seen within 24 hours of initiating therapy. To prevent overcorrection, the infusion should be stopped when the arterial pH decreases to 7.5.[7,61] ABGs and serum electrolytes should be drawn every 4 to 8 hours to evaluate and adjust therapy.

The dose of hydrochloric acid can be based on an estimate of the total body chloride deficit:[61]

$$\text{Dose HCl(in mEq or mmol)}=[0.2\ \text{L/kg}\times\text{BW(in kg)}]\times[103\text{-observed serum chloride}]$$
Dose HCl(in mEq or mmol)=[0.2 L/kg×BW(in kg)]×[103-observed serum chloride]

where the estimated chloride space is 0.2 times the BW, and the average serum chloride is 103 mEq/L (mmol/L). Alternatively, the dose can be calculated based on the estimated base deficit:[8,63]

$$\text{Dose HCl (in mEq or mmol)}=[0.5\ \text{L/kg}\times\text{BW (in kg)}]\times(\text{desired}[\text{HCO}_3^-]\text{-observed}[\text{HCO}_3^-])$$
Dose HCl (in mEq or mmol)=[0.5 L/kg×BW (in kg)]×(desired[HCO3-]-observed[HCO3-])

Ammonium Chloride

Ammonium chloride has a limited role in the treatment of metabolic alkalosis. The liver converts ammonium chloride (NH_4Cl) to urea and free hydrochloric acid:[64]

$$2\text{NH}_4\text{Cl}+2\text{HCO}_3^-\rightarrow\text{CO(NH}_2)_2\_\text{CO}_2+3\text{H}_2\text{O}+2\text{Cl}^-$$
2NH4Cl+2HCO3-⟶CO(NH2)2_CO2+3H2O+2Cl-

The dose of ammonium chloride can be calculated based on the chloride deficit using the same method as for HCl and assuming that 20 g ammonium chloride will provide 374 mEq (mmol) of H^+. However, only one-half of the calculated dose of ammonium chloride should be administered to avoid ammonia toxicity. Ammonium chloride is available as a 26.75% solution containing 100 mEq (mmol) of H^+ in 20 mL, which should be further diluted prior to administration. A dilute solution can be prepared by adding 20 mL of ammonium chloride to 500 mL of normal saline and infusing the solution at a rate of no more than 1 mEq/min (mmol/min). Improvement in metabolic status is usually seen within 24 hours. CNS toxicity, marked by confusion, irritability, seizures, and coma, has been associated with more rapid rates of administration. Ammonium chloride must be administered cautiously to patients with impaired kidney or hepatic function. In patients with impaired hepatic function, decreased conversion of ammonia to urea can result in increased ammonia levels and worsened encephalopathy. In patients with kidney disease, the increased urea synthesis can exacerbate uremic symptoms.[63,64]

Arginine Monohydrochloride

Although not FDA-approved, arginine monohydrochloride at a dose of 10 g/hr given IV has been used to treat metabolic alkalosis. Like ammonium chloride, arginine must undergo metabolism by the liver to produce hydrogen ions, with a conversion of 100 g to 475 mEq (mmol) of H^+. Unlike ammonium chloride, arginine combines with ammonia in the body to synthesize urea; thus, it can be used in patients with relative hepatic insufficiency. Patients with kidney disease should not receive arginine monohydrochloride because it can significantly elevate blood urea nitrogen and is associated with severe hyperkalemia.[64,65] The increase in potassium is caused by arginine-induced shifts of potassium from the intracellular to the extracellular space.

Sodium Chloride–Resistant Metabolic Alkalosis

⑬ Management of these disorders usually consists of treatment of the underlying cause of the mineralocorticoid excess. For patients taking a corticosteroid, a dosage reduction or a switch to a corticosteroid with less mineralocorticoid activity (eg, methylprednisolone) should be considered. Patients with an endogenous source of excess mineralocorticoid activity can require surgery or the administration of spironolactone, amiloride, or triamterene.[2,52]

Spironolactone is a competitive antagonist of the mineralocorticoid receptor. Amiloride and triamterene are potassium-sparing diuretics that inhibit the epithelial sodium channel in the distal convoluted tubule and collecting duct. All three agents inhibit aldosterone-stimulated sodium reabsorption in the collecting duct. In addition, spironolactone directly inhibits aldosterone stimulation of the hydrogen ion secretory pump. Thus, most patients with mineralocorticoid excess, including Bartter and Gitelman syndromes, respond to therapy with these agents.[7] Liddle syndrome, which is a form of pseudohypoaldosteronism caused by overactivity of the epithelial sodium channel, is not responsive to spironolactone but can be treated with either amiloride or triamterene.[52] Although experience is limited, some patients with Bartter and Gitelman syndromes may respond to NSAIDs or ACE inhibitors.[7,66,67] Finally, aggressive potassium repletion can correct the alkalosis in those who have not responded to the approaches outlined above (see Chapter 70).

RESPIRATORY ACID–BASE DISORDERS

As with the metabolic acid–base disturbances, there are two cardinal respiratory acid–base disturbances: respiratory acidosis and respiratory alkalosis. These disorders are generated by a primary alteration in CO_2 excretion, which changes the concentration of CO_2, and therefore the carbonic acid concentration in body fluids.[4] A primary reduction in $PaCO_2$ causes an increase in pH (respiratory alkalosis), and a primary increase in $PaCO_2$ causes a decrease in pH (respiratory acidosis). Unlike the metabolic disturbances, for which respiratory compensation is rapid, metabolic compensation for the respiratory disturbances is slow. Hence, these disturbances can be further divided into acute disorders, with a duration of minutes to hours, and where metabolic compensation has yet to occur, and chronic disorders that have been present long enough for metabolic compensation to be complete.

Respiratory Alkalosis

Respiratory alkalosis is characterized by a primary decrease in $PaCO_2$ that leads to an elevation in pH. The $PaCO_2$ decreases when the excretion of CO_2 by the lungs exceeds the metabolic production of CO_2. It is the most frequently encountered acid–base disorder, occurring physiologically in normal pregnancy and in persons living at high altitudes.[68] Respiratory alkalosis also occurs frequently among hospitalized patients (Table 71-12).[68,69]

TABLE 71-12

Causes of Respiratory Alkalosis

Medications (stimulation of central nervous system respiration)	Xanthine derivatives (theophylline, aminophylline, caffeine)
	Nicotine
	Catecholamines (epinephrine, norepinephrine, dopamine)

A decrease in $PaCO_2$ occurs when ventilatory excretion exceeds metabolic production. Because endogenous production of CO_2 is relatively constant, negative CO_2 balance is primarily caused by an increase in ventilatory excretion of CO_2 (hyperventilation). The metabolic production of CO_2, however, can be increased during periods of stress or with excess carbohydrate administration (eg, parenteral nutrition). Hyperventilation can develop from an increase in neurochemical stimulation via either central or peripheral mechanisms, or by the result of voluntary or mechanical (iatrogenic) hyperventilation.

A decrease in $PaCO_2$ can occur in patients with cardiogenic, hypovolemic, or septic shock because oxygen delivery to the carotid and aortic chemoreceptors is reduced. This relative deficit in PaO_2 stimulates an increase in ventilation. The hyperventilation in sepsis is also mediated via a central mechanism. Hyperventilation-induced respiratory alkalosis with an elevation in cardiac index and hypotension without peripheral vasoconstriction can therefore be an early sign of sepsis.

Clinical Presentation

Although most patients are asymptomatic, respiratory alkalosis can cause adverse neuromuscular, cardiovascular, and GI effects.[68] During periods of decreased $PaCO_2$, there is a decrease in cerebral blood flow, which can be responsible for symptoms of light-headedness, confusion, decreased intellectual functioning, syncope, and seizures. Nausea and vomiting can occur, probably as a result of cerebral hypoxia. In severe respiratory alkalosis, cardiac arrhythmias can occur because of sensitization of the myocardium to the arrhythmogenic effects of circulating catecholamines.[70] Acute respiratory alkalosis has no effect on BP or cardiac output in awake individuals. Anesthetized patients, however, can experience a decrease in both cardiac output and BP, possibly owing to the lack of a tachycardic response.[68]

The concentration of serum electrolytes can also be altered secondary to the development of respiratory alkalosis.[7] The serum chloride concentration is usually slightly increased, and serum potassium concentration can be slightly decreased. Clinically significant hypokalemia can be a consequence of extreme respiratory alkalosis, although the effect is usually very small or negligible.[71] Serum phosphorus concentration can decrease by as much as 1.5 to 2 mg/dL (0.48-0.65 mmol/L) because of the shift of inorganic phosphate into cells. Reductions in the blood ionized calcium concentration can be partially responsible for symptoms such as muscle cramps and tetany. Approximately 40% of calcium is bound to albumin, and an increase in pH results in an increase in binding.[72]

Compensation

The initial response of the body to acute respiratory alkalosis is chemical buffering: hydrogen ions are released from the body's buffers—intracellular proteins, phosphates, and hemoglobin—and titrate down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L (mmol/L) for each 10-mm Hg (1.3 kPa) decrease in $PaCO_2$ (see Table 71-8).[7] When only physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited, and the serum bicarbonate concentration decreases. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia as well as decreased NH_4^+ and titratable acid excretion are direct effects of the reduced $PaCO_2$ and pH on renal reabsorption of chloride and bicarbonate.[2,73] The acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 71-8). In fully compensated respiratory alkalosis, the bicarbonate concentration decreases by 4 mEq/L (mmol/L) below 24 for each 10-mm Hg (1.3 kPa) drop in $PaCO_2$. For example, a sustained decrease in $PaCO_2$ of 20 mm Hg (2.7 kPa) will lower serum bicarbonate from 24 to 16 mEq/L (mmol/L) with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid–base disorder.

TREATMENT OF RESPIRATORY ALKALOSIS

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild (pH not exceeding 7.5), treatment is often not required.[70] The first consideration in the treatment of acute respiratory alkalosis with pH more than 7.5 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with IV fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures can prove effective. A rebreathing device, such as a paper bag, can be useful in controlling hyperventilation in patients with the anxiety/hyperventilation syndrome. Oxygen therapy should be initiated in patients with severe hypoxemia.[68,70] Patients with life-threatening alkalosis (pH more than 7.55), particularly if it is a mixed respiratory and metabolic condition, tend to have complications, such as arrhythmias or seizures, which can require mechanical ventilation with sedation and/or paralysis to control hyperventilation.[64,68]

Respiratory alkalosis in patients receiving mechanical ventilation is usually iatrogenic. It can often be corrected by decreasing either the set RR or tidal volume, although other measures can also be employed. The use of a capnograph and spirometer in the breathing circuit enables a more precise adjustment of the ventilator settings. Another method of treating respiratory alkalosis is to increase the amount of dead space in the ventilator circuit by placing a known length of tubing between the artificial airway and the "T" piece of the ventilator. This results in "rebreathing" of expired gas, and therefore an increase in the inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis can be employed.

CLINICAL PRESENTATION: Respiratory Alkalosis

General

- The patient is usually asymptomatic if the condition is chronic and mild.

Symptoms

- The patient may complain of light-headedness, confusion, muscle cramps and tetany, and decreased intellectual functioning.
- Nausea and vomiting can occur, probably as a result of cerebral hypoxia.

Signs

- In severe respiratory alkalosis, pH is more than 7.55.

Laboratory Tests

- Serum chloride concentration is usually slightly increased. Serum ionized calcium through increased calcium binding to albumin, potassium, and phosphorus concentration can be decreased.

Respiratory Acidosis

Pathophysiology

Respiratory acidosis occurs when the lungs fail to excrete CO_2 resulting in a lower pH. This can be the result of conditions that centrally inhibit the respiratory center, diseases that interfere with pulmonary perfusion or neuromuscular function, and intrinsic airway or parenchymal pulmonary disease (Table 71-13).[68,69] Acute respiratory acidosis with hypoxemia, hypercarbia, and acidosis is life threatening. Those disorders that produce an increase in $PaCO_2$ and hypoxemia to a degree compatible with life (eg, chronic obstructive pulmonary disease), with or without oxygen therapy, can result in chronic respiratory acidosis (Table 71-14).[68,69] These patients can function normally without noticeable neurologic defects with higher than normal range $PaCO_2$ concentrations, provided that adequate oxygenation is maintained.

TABLE 71-13

Causes of Acute Respiratory Acidosis

Airway and pulmonary abnormalities	Acute airway obstruction

	Acute asthma exacerbation
	Acute cardiogenic pulmonary edema
	Acute respiratory distress syndrome
	Aspiration
	Chronic obstructive pulmonary disease exacerbation
	Obesity hypoventilation syndrome

	Multiple sclerosis
	Poliomyelitis
	Primary alveolar hypoventilation syndrome
	Tumors
Pulmonary abnormalities/disorders	Bronchitis
	Chronic obstructive pulmonary disease
	Chronic pulmonary embolism
	Emphysema
	Extreme obesity
	Fibrothorax
	Kyphoscoliosis
	Pulmonary fibrosis

Clinical Presentation

Respiratory acidosis can produce neurologic symptoms, including altered mental status, abnormal behavior, seizures, stupor, and coma. Hypercapnia can mimic stroke or CNS tumors by producing headache, papilledema, focal paresis, and abnormal reflexes. These CNS symptoms are attributable to the vasodilator effects of CO_2 in the brain that result in an increase in cerebral blood flow.[2] The CNS response to hypercapnia is extremely variable between patients and is most influenced by the acuity of presentation. Given that chronic hypercapnia blunts the usual respiratory stimulus of an elevated $PaCO_2$, hypoxemia rather than hypercapnia provides the primary ventilatory stimulus in patients with severe chronic respiratory acidosis.[18]

The degree to which cardiac contractility and HR are altered depends on the severity of the acidosis and the rapidity with which it develops. Modest acute hypercapnia ($PaCO_2$ of 50-55 mm Hg [6.7-7.3 kPa]) stimulates a stress-like response, with elevated catecholamines and corticosteroid hormone levels, and can result in increased cardiac output and pulmonary artery pressure. As the severity increases, cardiac output declines and vascular resistance decreases leading to refractory hypotension in some patients.[68]

In respiratory acidosis, the serum potassium concentration increases modestly secondary to cellular shifts. The increases are less than those seen with inorganic metabolic acidosis and are difficult to predict for individual patients.[71]

Compensation

The body responds to acute respiratory acidosis with chemical buffering. The increase in $PaCO_2$ results in increased carbonic acid levels. The carbonic acid dissociates, releasing hydrogen ions, which are buffered by non-bicarbonate buffers (ie, proteins, phosphate, and hemoglobin) and bicarbonate. Thus, based on physicochemical factors, increases in $PaCO_2$ raise the serum bicarbonate concentration. In general, in acute respiratory acidosis, the bicarbonate concentration increases by 1 mEq/L (mmol/L) above 24 for each 10 mm Hg (1.3 kPa) increase in $PaCO_2$ above 40 mm Hg (5.3 kPa) (see Table 71-8).[7]

CLINICAL PRESENTATION: Respiratory Acidosis

General

- The patient is usually symptomatic.

Symptoms

- The patient may complain of confusion or difficulty thinking and headache.

Signs

- In severe respiratory acidosis.
- Cardiac: Increased cardiac output if moderate that decreases if severe. Refractory hypotension can be present in some patients.
- CNS: Abnormal behavior, seizures, stupor, and coma. Papilledema, focal paresis, and abnormal reflexes can also be present.

Laboratory Tests

- Serum potassium concentration can be modestly increased. Hypercapnia can be moderate ($PaCO_2$ of 50-55 mm Hg [6.7-7.3 kPa]) to severe ($PaCO_2$ of more than 80 mm Hg [10.6 kPa]). Hypoxia (PaO_2 is less than 70 mm Hg [9.3 kPa]) is often present.

Metabolic compensation occurs when respiratory acidosis is prolonged beyond 12 to 24 hours. In response to hypercapnia and acidemia, proximal tubular bicarbonate reabsorption, ammoniagenesis, and distal tubular hydrogen secretion are enhanced, resulting in an increase in the serum bicarbonate concentration that raises the pH toward normal. Renal compensation for chronic hypercapnia generally results in the plasma bicarbonate concentration increasing by 4 mEq/L (mmol/L) above 24 for each 10 mm Hg (1.3 kPa) increase in $PaCO_2$ above 40 mm Hg (5.3 kPa) (see Table 71-8).[7] The new steady state in acid–base values is generally achieved within 5 days of the onset of hypercapnia in dogs; the time interval necessary for compensation in humans has not been established.[74]

TREATMENT OF RESPIRATORY ACIDOSIS

The treatment of respiratory acidosis is dependent on the chronicity of the patient's condition. Respiratory decompensation in patients with chronic elevations in $PaCO_2$ is frequently seen in those with acute infections and those recently started on narcotic analgesics or oxygen therapy. Aggressive treatment of these conditions can offer considerable benefit and should be initiated. Furthermore, tranquilizers and sedatives should be avoided and supplemental oxygen, if used, should be minimized.[68]

Acute Respiratory Acidosis

When carbon dioxide excretion is severely impaired ($PaCO_2$ more than 80 mm Hg [10.6 kPa]) and/or life threatening, hypoxia is present (PaO_2 less than 40 mm Hg [5.3 kPa]); the immediate therapeutic goal is to provide adequate oxygenation. Under these circumstances, hypoxia, not acidemia, is the principal threat to life. A patent airway needs to be established, which can necessitate intubation. Excessive secretions must be cleared from the airway and oxygen administered to restore adequate oxygenation. Mechanical ventilation is usually required.

⑭ The underlying cause of the acidosis should be treated aggressively (ie, bronchodilators for treatment of severe bronchospasm; narcotic or benzodiazepine antagonists to reverse the deleterious effects of these agents on the respiratory center). Bicarbonate administration is rarely necessary in the treatment of respiratory acidosis. Furthermore, rapid correction of acidosis with bicarbonate can eliminate the patient's respiratory drive or precipitate metabolic alkalosis. Cautious use of alkali (bicarbonate) can restore the responsiveness of bronchial muscles to β-adrenergic agonists and thus can be beneficial for those patients with severe bronchospasm.[74] ABGs should be monitored closely to ensure that the respiratory acidosis is resolving without creating a metabolic alkalosis as the result of compensatory elevation in HCO_3^- and decrease in $PaCO_2$. ABGs should be obtained every 2 to 4 hours during the acute phase and less frequently (every 12-24 hours) as the acidosis improves.

Acute Respiratory Acidosis in a Compensated Chronic Respiratory Acidotic Patient

Patients with a history of chronic respiratory acidosis (eg, those with chronic obstructive pulmonary disease) can experience an acute worsening of their respiratory acidosis. This can result in severe life-threatening hypoxemia. As with acute respiratory acidosis, the goals of therapy are maintenance of a patent airway and adequate oxygenation. Individuals with chronic respiratory acidosis are routinely able to tolerate a low PaO_2 and an elevated $PaCO_2$ because of compensation (increased number of red blood cells, hemoglobin content, and 2,3-diphosphoglycerate). The drive to breathe in these patients is dependent on hypoxemia rather than hypercarbia. Administration of oxygen to a patient with chronic respiratory acidosis can eliminate this drive to breathe and result in the syndrome of carbon dioxide narcosis. In this case, if the PaO_2 is 50 mm Hg (6.7 kPa), no oxygen treatment is necessary. If the PaO_2 is less than 50 mm Hg (6.7 kPa), oxygen therapy should be initiated carefully using a controlled flow of oxygen.[68]

ABGs should be checked periodically to ensure adequate oxygenation. If the $PaCO_2$ increases during oxygen therapy, it can be a sign of impending carbon dioxide narcosis and oxygen therapy may need to be discontinued. The underlying cause of the acute exacerbation should be aggressively managed. Pulmonary infections should be treated with the appropriate antibiotics and bronchodilators administered as necessary. Excess secretions should be cleared from the airway to allow proper gas exchange. This can involve increasing oral fluid intake to decrease the viscosity of secretions, deep breathing, and postural drainage, suction, or bronchoscopy.

MIXED ACID–BASE DISORDERS

Diagnosis

The diagnosis of a mixed disorder depends on an understanding of the appropriate quantitative response of the compensatory mechanisms for each of the simple acid–base disturbances.[38,75] To diagnose mixed disorders, one must know how each of the four simple disorders alters pH, $PaCO_2$, and

(HCO_3^-) (see Table 71-8). If a given set of blood gases does not decrease within the range of expected responses for a simple acid–base disturbance, a mixed disorder should be suspected. In addition to laboratory information, a thorough history and physical examination of the patient will often lead to the diagnosis, even before the laboratory data are available. Examples of common mixed disturbances follow.

Mixed Respiratory Acidosis and Metabolic Acidosis

A mixed respiratory and metabolic acidosis disturbance is characterized by a failure of compensation. The respiratory disorder prevents the compensatory decrease in $PaCO_2$ expected in the defense against metabolic acidosis. The metabolic disorder prevents the buffering and renal mechanisms from raising the bicarbonate concentration as expected in the defense against respiratory acidosis. In the absence of these compensatory mechanisms, the pH decreases markedly.

Mixed respiratory and metabolic acidosis may develop in patients with cardiorespiratory arrest, in those with chronic lung disease who are in shock, and in metabolic acidosis patients who develop respiratory failure. When treating this mixed disorder, clinicians need to respond to both the respiratory and metabolic acidosis. Improved oxygen delivery must be initiated to improve hypercarbia and hypoxia. Mechanical ventilation may be needed to reduce $PaCO_2$. During the initial stage of therapy, appropriate amounts of alkali should be given to reverse the metabolic acidosis (see section "Treatment," for "Metabolic Acidosis").

Mixed Respiratory Alkalosis and Metabolic Alkalosis

The combination of respiratory and metabolic alkalosis is the most common mixed acid–base disorder. This mixed disorder occurs frequently in critically ill surgical patients with respiratory alkalosis caused by mechanical ventilation, hypoxia, sepsis, hypotension, neurologic damage, pain, or medications, and with metabolic alkalosis caused by vomiting or nasogastric suctioning and massive blood transfusions. It can also occur in patients with hepatic cirrhosis who hyperventilate, receive diuretics, or vomit, as well as in patients with chronic respiratory acidosis and an elevated plasma bicarbonate concentration who are placed on mechanical ventilation and undergo a rapid decrease in $PaCO_2$.

The renal excretion of bicarbonate that usually occurs as compensation for the respiratory alkalosis is prevented by the complicating metabolic alkalosis. Likewise, the retention of $PaCO_2$ expected to compensate for metabolic alkalosis is prevented by the primary respiratory alkalosis. The failure of compensation that occurs with mixed respiratory and metabolic alkalosis can result in a severe alkalemia.

Administration of sodium chloride and potassium chloride solutions will help correct the metabolic component of a mixed respiratory and metabolic alkalosis, and adjustment of the ventilator and/or treatment of an underlying process that is causing hyperventilation can correct or ameliorate the respiratory component of this mixed disorder.

Mixed Metabolic Acidosis and Respiratory Alkalosis

This mixed disorder is often seen in patients with advanced liver disease, salicylate intoxication, and pulmonary-renal syndromes. The respiratory alkalosis will decrease the $PaCO_2$ beyond the appropriate range for the respiratory compensation usually seen with metabolic acidosis. The plasma bicarbonate concentration also decreases below the level expected in compensation for a simple respiratory alkalosis. In a sense, the defense of pH for either disorder alone is enhanced; thus, the pH can be normal or close to normal, with a low $PaCO_2$ and a low (HCO_3^-). Treatment of this disorder should be directed at the underlying cause. Because of the enhanced compensation, the pH is usually closer to normal than in either of the two simple disorders.

Mixed Metabolic Alkalosis and Respiratory Acidosis

This mixed disorder often occurs in patients with chronic obstructive pulmonary disease and chronic respiratory acidosis who are treated with salt restriction, diuretics, and possibly glucocorticoids. When diuretics are initiated, the plasma bicarbonate may increase because of increased renal bicarbonate generation and reabsorption, providing mechanisms for both generating and maintaining metabolic alkalosis. The elevated pH diminishes respiratory drive and may therefore worsen the respiratory acidosis.

Although the pH may not deviate significantly from normal, treatment may need to be initiated to maintain PaO_2 and $PaCO_2$ at acceptable levels.

Because it is often difficult to correctly identify this mixed disorder, it is helpful to observe the patient's response to discontinuation of diuretics and administration of sodium and potassium chloride.[38] The $PaCO_2$ will normalize if the patient has a simple metabolic alkalosis, but it will be minimally affected in the setting of a mixed disorder. Treatment should be aimed at decreasing the plasma bicarbonate with sodium and potassium chloride therapy, thereby allowing the renal excretion of retained bicarbonate from the diuretic-induced metabolic alkalosis. This therapy should be used cautiously to avoid exacerbating any underlying chronic heart failure.

CONCLUSION

Acid–base disorders are a common and widespread problem, and clinicians can play a key role in identifying, preventing, and properly treating them. Acid–base disorders do not occur only in the intensive care unit setting. Patients in ambulatory and extended care settings have many chronic conditions and medication therapies that commonly affect acid–base balance. Thus, clinicians in all practice settings should strive to identify patients at high risk for developing medication-related problems that affect acid–base balance and to undertake appropriate prevention and treatment measures to improve the quality of life of their patients.

SELF-ASSESSMENT QUESTIONS

1. A 31-year-old man, LG, was found to be unresponsive and apneic and transferred to the emergency department. His arterial blood gas (ABG) sample on arrival revealed the following: pH 7.08, PCO_2 80 mm Hg (10.6 kPa), and HCO_3^- 23 mEq/L (mmol/L). His serum labs demonstrated Na 130 mEq/L (mmol/L); Cl 111 mEq/L (mmol/L), and TCO_2 23 mEq/L (mmol/L). His acid–base disturbance is:

   A. Respiratory acidosis with an elevated anion gap

   B. Respiratory acidosis with a normal anion gap

   C. Metabolic acidosis with a normal anion gap

   D. Metabolic acidosis with an elevated anion gap

2. A 31-year-old man, LG, was found to be unresponsive and apneic and transferred to the emergency department. His ABG sample on arrival revealed the following: pH 7.08, PCO_2 80 mm Hg (10.6 kPa), and HCO_3^- 23 mEq/L (mmol/L). His serum labs demonstrated Na 130 mEq/L (mmol/L); Cl 111 mEq/L (mmol/L), and TCO_2 23 mEq/L (mmol/L). Which statement is *most true* about extracellular buffering?

A. The bicarbonate buffer system is the most important because it is not dependent on the amount of bicarbonate filtered by the kidney.

B. The carbonic acid buffer system plays a minimal role given the low amount of CO_2 produced by the body.

C. The stomach plays an important role given its ability to easily adjust the amount of gastric acid produced.

D. The phosphate buffer system plays a limited role given the low concentrations of extracellular phosphate.

3. A 45-year-old female, AR, is transferred to the intensive care unit with septic shock due to acute peritonitis. Her ABG sample revealed the following: pH 7.25, PCO_2 29 mm Hg (3.9 kPa), and HCO_3^- 15 mEq/L (mmol/L). Her serum labs demonstrated Na 142 mEq/L (mmol/L); Cl 105 mEq/L (mmol/L), and TCO_2 15 mEq/L (mmol/L), lactate 5.8 mEq/L (mmol/L). Which statement is *most true* regarding the expected compensation for AR's acid–base disturbance?

A. Compensation is initiated within days through increased renal elimination of bicarbonate.

B. Compensation is initiated within hours through renal accumulation of bicarbonate.

C. Compensation is initiated within hours through increased respiratory rate.

D. Compensation is initiated within days through decreased respiratory rate.

4. A 68-year-old man, KL (weight: 70 kg; height: 69 in. [175 cm]), with a long-standing history of poorly controlled diabetes mellitus, is admitted to the medical floor of a hospital with a diagnosis of community-acquired pneumonia. His most recent ABG is as follows: pH 7.30, PCO_2 34 mm Hg (4.5 kPa), HCO_3^- 15 mEq/L (mmol/L), and PO_2 80 mm Hg (10.6 kPa), and his most recent serum labs demonstrate Na 135 mEq/L (mmol/L), K 5.4 mEq/L (mmol/L), Cl 116 mEq/L (mmol/L), TCO_2 15 mEq/L (mmol/L), and blood glucose 146 mg/dL (8.1 mmol/L). He is hemodynamically stable. His acid–base disturbance is:

A. Respiratory alkalosis

B. Metabolic alkalosis

C. Respiratory acidosis

D. Metabolic acidosis

5. A 68-year-old man, KL, with a long-standing history of poorly controlled diabetes mellitus, is admitted to the medical floor of a hospital with a diagnosis of community-acquired pneumonia. His most recent ABG is as follows: pH 7.30, PCO_2 34 mm Hg (4.5 kPa), HCO_3^- 15 mEq/L (mmol/L), and PO_2 80 mm Hg (10.6 kPa), and his most recent serum labs demonstrate Na 135 mEq/L (mmol/L), K 5.4 mEq/L (mmol/L), Cl 116 mEq/L (mmol/L), TCO_2 15 mEq/L (mmol/L), blood urea nitrogen 23 mg/dL (8.2 mmol/L), SCr 1.5 mg/dL (133 µmol/L) and blood glucose 146 mg/dL (8.1 mmol/L). He is hemodynamically stable. Which condition *best* explains his current acid–base status?

A. Type IV renal tubular acidosis

B. Diabetic ketoacidosis

C. Type II renal tubular acidosis (proximal)

D. Type I renal tubular acidosis (distal)

6. A 68-year-old man, KL, with a long-standing history of poorly controlled diabetes mellitus, is admitted to the medical floor of a hospital with a diagnosis of community-acquired pneumonia. His most recent ABG is as follows: pH 7.30, PCO_2 34 mm Hg (4.5 kPa), HCO_3^- 15 mEq/L (mmol/L), and

PO_2 80 mm Hg (10.6 kPa), and his most recent serum labs demonstrate Na 135 mEq/L (mmol/L), K 5.4 mEq/L (mmol/L), Cl 116 mEq/L (mmol/L), TCO_2 15 mEq/L (mmol/L), and blood glucose 146 mg/dL (8.1 mmol/L). KL is found to be hypertensive (BP 170/92 mm Hg) and the medical resident asks if there is an antihypertensive that should be avoided in KL based on the underlying condition contributing to KL's current acid–base status. Which agent should be *avoided* in KL at this time?

A. Enalapril

B. Clonidine

C. Hydralazine

D. Amlodipine

7. A 44-year-old moderately dehydrated female was admitted with a two-day history of acute severe diarrhea. Her most recent ABG is as follows: pH 7.31, PCO_2 28 mm Hg (3.7 kPa), pO_2 93 mm Hg (12.4 kPa), HCO_3^- 16 mEq/L (mmol/L), O_2 saturation 94% [0.94], and her most recent serum labs demonstrate Na 134 mEq/L (mmol/L), K 3.1 mEq/L (mmol/L), Cl 108 mEq/L (mmol/L), TCO_2 15 mEq/L (mmol/L), BUN 31 mg/dL (11.1 mmol/L), creatinine 1.5 mg/dL (133 µmol/L). Baseline creatinine is 0.7 mg/dL (62 µmol/L). What is the *most appropriate* treatment of choice for this patient with normal anion gap metabolic acidosis?

A. Replace bicarbonate deficit with sodium bicarbonate intravenously during the first 24 hours of admission.

B. Replace ½ the bicarbonate deficit with sodium bicarbonate intravenously during the first 24 hours of admission.

C. Replace bicarbonate deficit with bicarbonate oral solution during the first 24 hours of admission.

D. Correct the underlying cause. Bicarbonate therapy not indicated.

8. Which of the following human immunodeficiency virus (HIV) medications has been *most* associated with lactic acidosis?

A. Rilpivirine

B. Efavirenz

C. Stavudine

D. Elvitegravir

9. Which statement is *most true* regarding RTA?

A. Distal RTA (type IV) can be caused by aldosterone resistance and often results in hypokalemia.

B. Proximal RTA (type II) is caused by a defect in the proximal tubule that prevents reabsorption of bicarbonate.

C. Proximal RTA (type II) and distal RTA (type I) are associated with sodium wasting and hypokalemia.

D. Renal tubular acidosis is usually associated with a high anion gap resulting from an increase in unmeasured anions.

10. A 31-year-old male presents with lethargy, weakness, confusion, and rapid breathing. He has had type 1 diabetes mellitus for 15 years and has been suffering from the "intestinal flu" for a day or so, for which he has been avoiding food to help prevent further vomiting and "make his stomachache go away." Since he stopped eating, he thought that it would be a good idea to stop taking his insulin. When seen in the emergency department his urine dipstick was positive for both glucose and ketones and his breath had a strange sweet, fruity smell. The following ABG data were obtained: pH 7.26, PCO_2 23 mm Hg (3.1 kPa), and HCO_3^- 10 mEq/L (mmol/L). His most recent serum chemistries are as follows: Na 140 mEq/L (mmol/L), Cl 100 mEq/L (mmol/L), K 4.5 mEq/L (mmol/L), TCO_2 11 mEq/L (mmol/L), and glucose 793 mg/dL (44 mmol/L). His acid–base disturbance is:

A. Metabolic alkalosis (normal anion gap) due to rapid breathing

B. Metabolic alkalosis (elevated anion gap) due to inadequate oral intake

C. Metabolic acidosis (normal anion gap) due to vomiting

D. Metabolic acidosis (elevated anion gap) due to diabetic ketoacidosis

11. Which statement is *most true* regarding lactic acidosis?

A. Frequently reported with linezolid therapy of less than 4 weeks duration

B. Increased risk with administration of propofol at a dose of 10 mcg/kg/min for one day

C. Is considered when the serum lactate concentration equals 2 mEq/L (mmol/L)

D. Increased risk with high dose lorazepam IV infusions in a patient with kidney failure

12. Which of the following is *most correct* regarding administration of IV sodium bicarbonate to a patient with septic shock who has a high anion gap metabolic acidosis and an arterial pH of 7.15?

A. Sodium bicarbonate use will reduce mortality.

B. Sodium bicarbonate use may paradoxically reduce intracellular pH.

C. Sodium bicarbonate use will reduce the efficacy of norepinephrine.

D. Sodium bicarbonate IV is indicated for a patient with a pH of 7.3.

13. A 77-year-old female presents to the Emergency Department with increased bilateral lower extremity swelling, fatigue, and dyspnea upon exertion consistent with heart failure exacerbation. Due to the COVID-19 pandemic, she has been eating more canned goods and ordering take out, so she doesn't have to go to the grocery store and risk exposure. Her heart failure is managed outpatient with furosemide, metoprolol, and lisinopril. She increased her furosemide to twice daily dosing 5 days ago. Her most recent ABG is as follows: pH 7.51, PCO_2 48 mmHg (6.4 kPa), HCO_3^- 40 mEq/L (mmol/L), and PO_2 85 mm Hg (11.3 kPa), and her most recent serum labs demonstrate Na 133 mEq/L (mmol/L), K 3 mEq/L (mmol/L), Cl 91 mEq/L (mmol/L), and TCO_2 40 mEq/L (mmol/L). Urine chloride is less than 10 mEq/L (mmol/L). Her acid–base disturbance is:

A. Acute respiratory alkalosis

B. Saline responsive metabolic alkalosis

C. Saline resistant metabolic alkalosis

D. Chronic respiratory alkalosis

14. A 61-year-old female comes into your emergency department with sudden pain and swelling of her left wrist. She is status post stem cell transplant requiring high dose prednisone to help with skin graft-versus-host disease. What type of acid–base disorder can result from this therapy?

A. Saline-resistant metabolic alkalosis

B. Saline-responsive metabolic alkalosis

C. Anion gap metabolic acidosis

D. Non-anion gap metabolic acidosis

15. A patient is admitted to the ICU after emergency surgery for bowel perforation. He has been given 3 liters of 0.9% sodium chloride in the operating

room and 2 additional liters over the previous 2 hours. He has recently become drowsy and his respirations have slowed after receiving multiple doses of fentanyl IV for pain. The ABG is as follows: pH 7.29, PCO_2 34 mmHg (4.5 kPa), pO_2 98 mmHg (13.1 kPa), HCO_3^- 14 mEq/L (mmol/L) and the most recent lab values are as follows: Na 137 mEq/L (mmol/L), K 3.9 mEq/L (mmol/L), Cl 115 mEq/L (mmol/L), and TCO_2 15 mEq/L (mmol/L). The acid–base disturbance is:

A. Metabolic alkalosis with respiratory alkalosis

B. Metabolic alkalosis with respiratory acidosis

C. Metabolic acidosis with respiratory alkalosis

D. Metabolic acidosis with respiratory acidosis

SELF-ASSESSMENT QUESTION-ANSWERS WITH RATIONALES

1. **B.** Respiratory acidosis with a normal anion gap. The pH is less than 7.35 indicating acidosis. The PCO_2 is elevated (greater than 40 mm Hg [5.3 kPa]), indicating primary respiratory disorder. The anion gap is calculated as AG = $Na^+ - (Cl^- + HCO_3^-)$ = 130 mEq/L – (111 mEq/L + 23 mEq/L) = –4 (normal). The etiology is hypoventilation due to the patient being unresponsive and apneic leading to hypercarbia and respiratory acidosis.

2. **D.** The phosphate buffer system plays a limited role given the low concentrations of extracellular phosphate. Since extracellular phosphate is present in low concentrations, its usefulness as an extracellular buffering system is limited. The bicarbonate/carbonic acid buffer system is the most important buffer system in the body as there is a high concentration of extracellular bicarbonate compared to other buffer components, high amount of CO_2 produced in the body, and the extracellular fluid acidity can be regulated by either adjustments in bicarbonate concentration by the kidneys or adjustments of PCO_2 by the lungs. Gastric acid production in the stomach isn't involved in acid–base regulation. See Regulation of acid–base homeostasis (Extracellular buffering) section for more information.

3. **C.** Compensation is initiated within hours through increased RR. This patient is presenting with elevated anion gap metabolic acidosis due to septic shock. In such cases, the lungs will increase the RR which decreases the PCO_2 in order to restore the pH to normal. Respiratory compensation begins within minutes to hours.

4. **D.** Metabolic acidosis. pH is less than 7.35 indicating acidosis. The HCO_3^- is low (less than 24 mmol/L) indicating primary metabolic disorder. The calculated AG = 135 mEq/L – (116 mEq/L + 15 mEq/L) = 4 which is considered normal.

5. **A.** Type IV renal tubular acidosis. This patient has a normal anion gap AG = 135 mEq/L – (116 mEq/L + 15 mEq/L) = 4. Renal tubular acidosis is a type of normal anion gap metabolic acidosis. The presentation of a mild acidosis (mild decrease in serum TCO_2) and elevated serum potassium fits the classification of Type IV renal tubular acidosis. Type I and II renal tubular acidosis present with low or normal serum potassium and a lower serum bicarbonate. Diabetic ketoacidosis presents as an elevated anion gap metabolic acidosis.

6. **A.** Enalapril. The underlying etiology of Type IV RTA is aldosterone deficiency or aldosterone resistance and present with hyperkalemia. Due to this, medications such as ACE inhibitors should be avoided. The other antihypertensive agents do not work within the renin–angiotensin–aldosterone system and do not potentiate hyperkalemia.

7. **D.** Correct the underlying cause – bicarbonate therapy not indicated. This patient does not have an indication for IV sodium bicarbonate due to pH (pH greater than 7.2) and current clinical condition. Fluid resuscitation (e.g., balanced crystalloid) and treatment for diarrhea is indicated.

8. **C.** Stavudine is a nucleoside-analog transcriptase inhibitor (NRTI) associated with lactic acidosis. The proposed mechanism of NRTI lactic acidosis is inhibition of DNA polymerase gamma, an enzyme responsible for mitochondrial DNA synthesis. Rilpivirine, efavirenz are non-nucleoside reverse transcriptase inhibitors (NNRTIs) and elvitegravir is an integrase inhibitor.

9. **B.** Proximal RTA (Type II) is caused by a proximal tubular defect resulting in decreased reabsorption of bicarbonate into the urine. Distal RTA (Type

IV) can be caused by aldosterone resistance but often results in hyperkalemia. Proximal (Type II) is associated with sodium wasting and hypokalemia. Distal RTA (Type I) is associated with hypokalemia but not sodium wasting. RTA is classified as a normal anion gap metabolic acidosis.

10. **D.** Metabolic acidosis (elevated anion gap) due to diabetic ketoacidosis. pH is less than 7.35 indicating acidosis. The HCO_3^- is low (less than 24 mmol/L) indicating primary metabolic disorder. The anion gap is calculated using the equation AG = Na^+ - (Cl^- + HCO_3^-). Using the laboratory values provided, the calculated AG = 140 mEq/L – (100 mEq/L + 11 mEq/L) = 29 which is elevated. All of these plus the presence of ketones in the urine dipstick, fruity breath, history of type 1 diabetes mellitus, stopping insulin therapy, and glucose of 793 mg/dL (32.9 mmol/L) lead to the diagnosis of diabetic ketoacidosis.

11. **D.** Increased risk with high-dose lorazepam IV infusions in a patient with kidney failure. Lorazepam IV is formulated in propylene glycol diluent and high doses in patients with renal and/or hepatic dysfunction can lead to lactic acidosis as it is predominantly metabolized to lactic acid via hepatic alcohol dehydrogenase. Linezolid is rarely seen with short-term therapy. Propofol-related infusion syndrome is seen with prolonged, high-dose infusions (greater than 80 mcg/kg/min for greater than 48 hours). Lactic acidosis is considered when lactate concentrations exceed 4-5 mEq/L (mmol/L).

12. **B.** Sodium bicarbonate use may paradoxically reduce intracellular pH. The carbon dioxide produced after IV infusion of sodium bicarbonate diffuses more readily over the cell membrane to the intracellular compartment compared to bicarbonate. This can lead to a paradoxical reduction in intracellular pH and produces an increased risk for intracellular acidosis adverse medication reactions. Sodium bicarbonate use has not shown to provide a mortality benefit. Severe acidosis may limit efficacy of norepinephrine due to reduced vascular responsiveness and reduction in cardiac contractility. Sodium bicarbonate IV is indicated in severe metabolic acidosis defined as a pH less than 7.2.

13. **B.** Saline responsive metabolic alkalosis. pH is greater than 7.45 indicating alkalosis. The HCO_3^- is high (greater than 24 mmol/L) indicating primary metabolic process. The urine chloride is less than 10 mEq/L (mmol/L), indicating saline responsive. Etiology is increased furosemide dosing.

14. **A.** Saline-resistant metabolic alkalosis. High-dose steroids can result in mineralocorticoid excess causing significant renal H^+ and K depletion.

15. **D.** Metabolic acidosis with respiratory acidosis. pH is less than 7.4 indicated acidosis. PCO_2 is less than 40 mm Hg (5.3 kPa) and HCO_3^- is less than 24 mEq/L (mmol/L), indicating metabolic process. Anion gap is calculated as Na – (Cl + CO_2) = 137 mEq/L – (115 mEq/L + 15 mEq/L) = 7 (normal anion gap). Using the expected PCO_2 equation to determine appropriate compensation and possible mixed acid–base disorder, the calculated expected PCO_2 is 40 - [1.2 x (24 - measured TCO_2)] = 29 mmHg (or 5.3 kPa-[0.16 x(24-measured TCO_2)]= 3.9 kPa). The actual PCO_2 of 34 mm Hg (4.5 kPa) is greater than the expected PCO_2 of 29 mm Hg (3.9 kPa), indicating a concomitant respiratory acidosis. Upon reviewing history and physical, the patient has a bowel perforation with possible ischemia, received large volume 0.9% sodium chloride infusion, has received multiple doses of IV opioid (fentanyl) with decreased respirations and drowsiness. Metabolic acidosis is due to bowel ischemia and large volume chloride-based IV fluid administration and respiratory acidosis is due to opioid-induced respiratory depression.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 73: Alzheimer Disease

Ericka L. Crouse; Kristin M. Zimmerman; Emily P. Peron; Lana J. Sargent; Sarah E. Hobgood

KEY CONCEPTS

KEY CONCEPTS

① Alzheimer disease (AD) is the most common cause of dementia, the prevalence of which increases with each decade of life.

② The etiology of AD is unknown, and current pharmacotherapy neither cures nor arrests its pathophysiology.

③ Amyloid plaques and neurofibrillary tangles (NFTs) are the pathologic hallmarks of AD; however, the definitive cause of this disease is yet to be determined.

④ AD affects multiple areas of cognition and is characterized by a gradual onset with a slow, progressive decline.

⑤ A thorough physical examination (including a neurologic examination), as well as laboratory and imaging studies, are required to rule out other disorders and diagnose AD before considering pharmacotherapy.

⑥ Pharmacotherapy for AD focuses on impacting three domains: (1) cognition, (2) neuropsychiatric symptoms, and (3) functional ability.

⑦ Nonmedication therapy and social support for the patient and family are the primary treatment interventions for AD.

⑧ Cholinesterase inhibitors and memantine are used to treat cognitive symptoms of AD; whereas immunotherapies may have the potential to be disease-modifying.

⑨ Aducanumab, an amyloid beta-directed antibody, was Food and Drug Administration (FDA) approved in 2021 for AD via accelerated approval. Donanemab was granted breakthrough therapy designation and is continuing to be evaluated.

⑩ Appropriate management of vascular disease risk factors may reduce the risk for developing AD and may prevent the worsening of dementia in people with AD.

⑪ A thorough behavioral assessment with careful examination of environmental factors should be conducted, and a plan put in place before initiating medication therapy for behavioral symptoms.

BEYOND THE BOOK

BEYOND THE BOOK

Visit the Mini-Cog website at http://mini-cog.com. At the top of the screen select from the "Mini-Cog Versions" drop-down menu the "Standardized Mini-Cog Instrument" tab:

1. Review the three-step process and scoring guidelines. You do not need to print this document, as you can simply draw a circle on a blank piece of paper for your partner to use while you take notes on a separate piece of paper.
2. Work with a classmate to practice administering the Mini-Cog to each other and scoring it accordingly.
3. If you get stuck or are not sure how to score an item, return to the "Mini-Cog Versions" drop-down menu and select "Administering the Mini-Cog" and/or "Scoring the Mini-Cog."
4. You may have questions after working through this exercise, perhaps related to test logistics or next steps. If that is the case, consider returning to the "Mini-Cog Versions" drop-down menu and visiting the "FAQs" page.

This activity is intended to increase your familiarity with a brief, freely available dementia screening tool that is often used in clinical settings and as part of the Medicare Annual Wellness Visit. The Mini-Cog can be administered by any health professional or trained lay health worker.

INTRODUCTION

"I now begin the journey that will lead me into the sunset of my life." Ronald Reagan

Dementia is an umbrella term used to define the loss of cognitive functioning—thinking, remembering, and reasoning—and behavioral abilities that interferes with a person's daily life and activities. Mild cognitive impairment (MCI) often proceeds dementia, but not all cases progress to dementia. There are a variety of diseases and pathologies that cause dementia, with Alzheimer disease (AD), which is a gradually progressive dementia affecting cognition, behavior, and functional status, being the most common. The exact pathophysiologic mechanisms underlying AD are not entirely known, and no cure exists.[1] Although medications may reduce AD symptoms for a time, the disease is eventually fatal.

Alzheimer disease profoundly affects the family as well as the patient. The need for supervision and assistance increases until the late stages of the disease, when people with AD become totally dependent on a caregiver for all basic needs. To address the growing AD crisis facing the United States, the first national strategic plan, the National Alzheimer's Plan, was released in 2012 with the goal of coordinating efforts across the federal government to prevent and treat AD, increase public awareness, and improve the quality of care and support for patients and their caregivers.[2] The US Department of Health and Human Services has since updated this strategic plan to include a timeline for achieving its goal to "develop effective prevention and treatment modalities by 2025."[2]

EPIDEMIOLOGY

① AD is the most common cause of dementia, accounting for 60% to 80% of cases, although multiple etiologies can result in dementia (Table 73-1).[3,4] This chapter focuses exclusively on dementia of the Alzheimer type. However, the reader is encouraged to use the nonpharmacologic approaches and management of behavioral problems outlined in this chapter as a general treatment approach for other types of dementia that may share similar features with AD.

TABLE 73-1

Common Types of Dementia

Alzheimer disease
Vascular dementia
Dementia with Lewy bodies
Mixed dementia
Others (eg, Parkinson disease dementia, Frontotemporal dementia, Huntington disease, Creutzfeldt–Jakob disease)
Potentially reversible causes of cognitive dysfunction (eg, normal pressure hydrocephalus, thyroid dysfunction, vitamin B_{12} deficiency, delirium, depression, Wernicke–Korsakoff syndrome, infectious and autoimmune encephalitis)

Data from References [2,5].

Approximately 6.2 million adults age 65 years and older in the United States have AD, and by the year 2050, this number is projected to double.[3] Factors determining age of onset and rate of progression remain largely undefined. Onset can be as early as age 30 years, resulting in the arbitrary age classifications of early-onset (younger than age 65 years) AD (EOAD) and late-onset (age 65 years and older) AD (LOAD).[3] Though increasing age is the greatest risk factor for AD, AD is not a normal part of aging.

In people age 65 years and older, survival following AD diagnosis is typically 4 to 8 years but may be as long as 20 years.[3] AD is the fifth leading cause of death for those age 65 years and older in the United States; however, death among people with AD is often not a direct result of the disease but rather the functional impairments that accompany it.[3] Among the most common causes of death in people with AD is pneumonia, possibly resulting from swallowing difficulties and immobility in the terminal stage of the disease.[3] Those diagnosed with AD spend, on average, more years in the most severe stage of the disease than any other stage, and much of this time is spent in a nursing home.[3]

ETIOLOGY

Genetics

② The exact etiology of AD is unknown; however, several genetic and environmental factors have been explored as potential causes. Genetic factors have been linked to both EOAD and LOAD, although dominantly inherited forms of AD account for less than 1% of cases.[6] More than half of early-onset, dominantly inherited cases of AD can be attributed to alterations on chromosomes 1, 14, or 21. These alterations largely impact the processing of a large membrane protein called amyloid precursor protein (APP). APP is typically broken down by three major secretase enzymes—α-, β-, and γ-secretase—into nonpathologic fragments as well as potentially pathologic 38 to 43 peptide-long β-amyloid peptide (Aβ) fragments. Of these enzymes, α-secretase is responsible for ensuring that APP is broken down into nonpathologic fragments. Relative alterations in the activity of β- and/or γ-secretase may prove pathologic.[7] As a result, these enzymes may be considered potential therapeutic targets.

Rare, autosomal dominant forms of EOAD have been found in *APP* and the presenilin genes (*PSEN1* and *PSEN2*). Scientists have identified more than 160 mutations in *PSEN1* and *PSEN2*, and these mutations result in increased activity of γ-secretase, which may yield larger and more harmful Aβ fragments.[8,9] The *APP* is encoded on chromosome 21. Only a small number of EOAD cases have been associated with mutations in the *APP* gene, resulting in overproduction of Aβ or an increase in the proportion of Aβ ending at peptide 42.[8,9] Presence of these mutations, however, is often indicative of disease development.

Genetic susceptibility to LOAD is primarily linked to the apolipoprotein E (*APOE*) genotype. Hypothetically, *APOE* (a cholesterol transport gene) may be implicated in the pathogenesis of the disease. There are three major subtypes or alleles of *APOE—*2*, **3*, and **4*. Inheritance of the *APOE*4* allele accounts for much of the genetic risk in LOAD.[10] The mechanism through which *APOE*4* confers an increased risk is unknown, although *APOE*4* is associated with factors that may contribute to AD pathology, such as abnormalities in mitochondria, cytoskeletal dysfunction, and low glucose usage.[11] The risk for AD is two- to threefold higher in individuals with one *APOE*4* allele and 12-fold higher in individuals with two *APOE*4* alleles compared to those with no *APOE*4* alleles.[11] Moreover, onset of symptoms occurs at a relatively younger age as compared with people having no *APOE*4* alleles or only one copy of *APOE*4* in their genotype.[11] The prevalence of individuals who carry two copies of the *APOE*4* alleles is only 2%, while the prevalence of those carrying one allele is 25%. The *APOE*4* allele is not diagnostic of AD, essential for disease presence, or indicative of future disease development. Additionally, the association between *APOE* genotype and AD differs based on ancestral background.[12]

Additional genetic explanatory factors continue to be investigated with a focus on differences in race and ethnicity. Genome-wide association studies (GWAS) have been done on large cohorts of healthy individuals and those with AD, which has led to the identification of more genetic variants. One with the highest post-GWAS research success is the ATP-binding cassette transporter A7, *ABCA7* gene.[13] Both *APOE* and *ABCA7* are involved in lipid metabolism and are the strongest heritable contributors for genetic risk.[14] Important research continues to explore the effects of genetic variations on cognitive function within diverse populations.

Environmental and Other Factors

A number of factors are associated with an increased risk of AD, including age, decreased reserve capacity of the brain (eg, reduced brain size, low educational level, reduced mental and physical activity), head injury, Down syndrome, depression, MCI, and risk factors for vascular disease (eg, hypercholesterolemia, hypertension, atherosclerosis, coronary heart disease, smoking, elevated homocysteine, obesity, metabolic syndrome, diabetes).[3,4,15] Whether these vascular risk factors are true causal risk factors for AD contributing to AD pathology, or whether they result in cerebrovascular pathology that, in turn, contributes to the symptoms of AD, remains to be established. The incidence of AD rises with increasing age, and AD may develop in individuals over the course of decades, suggesting that AD is a disease that likely develops throughout adulthood.[3] Of note, more females than males have AD.[3] While this may largely be a factor of females living longer than males, hypothetically, males who live to be older than 65 years may have better cardiovascular risk profiles than females of the same age; this is commonly referred to as "survival bias."[3] An analysis of the complex interactions between age, sex, vascular health, and AD is beyond the scope of this chapter.

PATHOPHYSIOLOGY

③ The signature lesions in AD include amyloid plaques and neurofibrillary tangles (NFTs) located in the cortical areas and medial temporal lobe structures of the brain.[1,15,16] Along with these lesions, degeneration of neurons and synapses as well as cortical atrophy occurs. It is unclear if or how these lesions are definitively implicated in the development of AD symptoms. This is particularly true as plaques and NFTs may also be present in other diseases, even in normal aging. Importantly, however, AD-affected subjects appear to have a higher burden of plaques and NFTs in their younger years compared to age-matched controls. Several mechanisms have been proposed to explain changes in the brain that result in symptoms of AD, including misfolding of proteins (Aβ aggregation and deposition leading to the formation of plaques and tangles), synaptic failure and depletion of neurotrophin and neurotransmitters, and mitochondrial dysfunction (oxidative stress, impaired insulin signaling in the brain, vascular injury, inflammatory processes, loss of calcium regulation, and defects in cholesterol metabolism).[1,10,16]

Amyloid Cascade Hypothesis

Cleavage of APP via β- and γ-secretase produces Aβ fragments that are 36 to 43 amino acids in length. Amyloid clearance pathways include degradation by enzymes such as neprilysin-1, phagocytosis by glial cells, or transportation into the vasculature. If not cleared, these soluble, monomeric Aβ fragments can aggregate. These aggregations can include soluble but toxic oligomers or protofibrils, or less soluble, larger, extracellular fibrils and plaques.[17,18] While less common than other Aβ peptides, $A\beta_{42}$ is prone to aggregation and plaque formation.[1,19] Amyloid can also aggregate in the perivascular space between neurons and vessels, as well as vascular smooth muscle and basement cell membranes, contributing to cerebrovascular damage.[17,18]

The amyloid cascade hypothesis states that there is an imbalance between the production and clearance of Aβ peptides resulting in their accumulation and aggregation, insoluble extracellular plaque formation, and ultimately the development of AD.[1,17,19] More recent versions of the amyloid cascade hypothesis assume that soluble oligomer and protofibril forms of Aβ that are not sequestered in plaques actually drive the disease by binding to cell surface receptors, metals, and cellular membranes.[1,17,19] Additionally, it is unknown whether the presence of Aβ in any of these forms is the primary pathology responsible for AD development, or whether these changes are a marker of an alternate pathology. If treatments that reduce Aβ production or remove brain Aβ fail to arrest disease progression in those with early or prodromal disease, it would argue amyloidosis is not the primary pathology in most individuals with AD.

Neurofibrillary Tangles

At the same time Aβ was being identified in plaques, other researchers found that NFTs are common in the cells of the hippocampus and cerebral cortex (regions implicated in AD symptoms) in people with AD. These NFTs are composed of abnormally hyperphosphorylated tau protein. Tau protein provides structural support to microtubules, the cell's transportation, and skeletal support system.[4] When tau filaments undergo abnormal phosphorylation at a specific site, they cannot bind effectively to microtubules, and the microtubules collapse. Without an intact system of microtubules, the cell cannot function properly and eventually dies. Hypothetically, soluble forms of Aβ may trigger initial tau phosphorylation. In general, NFT density correlates with severity of dementia; however, NFTs are found in other dementing illnesses besides AD and may represent a common method by which various inciting factors culminate in cell death.[16,17,20]

Inflammatory Mediators

Inflammatory or immunologic paradigms are additional hypotheses relevant to AD neurodegeneration.[1] Inflammatory/immunologic hypotheses argue that although Aβ may have direct neurotoxicity, at least some of Aβ toxicity might actually be an indirect consequence of an immune response mediated by Aβ protofibril–induced microglia activation and astrocyte recruitment. This inflammatory response may represent an attempt to clear amyloid; however, it is also associated with release of cytokines, nitric oxide, other radical species, and complement factors that can both injure neurons and promote ongoing inflammation.[1] Indeed, levels of multiple cytokines and chemokines are elevated in AD brains, and certain proinflammatory gene polymorphisms are reported to be associated with AD.[1,21]

Cholinergic Hypothesis

Multiple neuronal pathways are destroyed in AD and neuronal damage can be seen in conjunction with plaque structures.[1,16] Widespread cell dysfunction or degeneration results in a variety of neurotransmitter deficits, with cholinergic abnormalities being among the most prominent.[1,10] Loss of cholinergic activity correlates with AD severity. In the late stage of AD, the number of cholinergic neurons is reduced, and there is loss of nicotinic receptors in the hippocampus and cortex. Presynaptic nicotinic receptors control the release of acetylcholine as well as other neurotransmitters important for memory and mood, including glutamate, serotonin, and norepinephrine.[1,10]

The discovery of vast cholinergic cell loss led to the development of a cholinergic hypothesis of AD which targeted cholinergic cell loss as the source of memory and cognitive impairment in AD. Consequently, increasing cholinergic function would improve symptoms of memory loss. This approach is flawed because cholinergic cell loss is a secondary consequence of AD pathology, not the disease-producing event, and cholinergic neurons are only one of many neuronal pathways destroyed in AD. Simple addition of acetylcholine cannot compensate for the loss of neurons, receptors, and other neurotransmitters lost during the course of the illness. Thus, cholinergic therapies are used to minimize or improve symptoms through augmentation of cholinergic neurotransmission at remaining synapses.

Other Neurotransmitter Abnormalities

Although the cholinergic system has received particular attention in AD pharmaceutical research, deficits also exist in other neuronal pathways. For example, serotonergic neurons of the raphe nuclei and noradrenergic cells of the locus coeruleus are lost, while activity of dopamine-metabolizing monoamine oxidase type B is increased. In addition, abnormalities appear in glutamate pathways of the cortex and limbic structures, where a loss of neurons leads to a focus on excitotoxicity models as possible contributing factors to AD pathology.

Glutamate is the major excitatory neurotransmitter in the cortex and hippocampus. Many neuronal pathways essential to learning and memory use glutamate as a neurotransmitter, including the pyramidal neurons (a layer of neurons with long axons carrying information out of the cortex), hippocampus, and entorhinal cortex. Glutamate and other excitatory amino acid neurotransmitters have been implicated as potential neurotoxins in AD.[16] Dysregulated glutamate activity is thought to be one of the primary mediators of neuronal injury after stroke or acute brain injury. Although intimately involved in cell injury, the role of excitatory amino acids in AD is yet unclear; however, blockade of *N*-methyl-D-aspartate (NMDA) receptors decreases activity of glutamate in the synapse and may hypothetically lessen the degree of cellular injury in AD.

Apolipoprotein E

The fat-soluble transporter *APOE* is synthesized in the liver, central nervous system, and cerebrospinal fluid (CSF). It is responsible for transporting cholesterol in the blood through the brain and interacts with Aβ in almost all pathways, including in its neuronal, glial, and vascular clearance. It is carried by low-density lipoprotein into neurons where it also binds to NFTs. The *APOE*4* allele, previously discussed under genetics, is associated with both modified clearance and increased deposition of Aβ in AD. It is also thought to act as an accelerating modulator in vascular dementia. The *APOE*4* allele is considered a strong risk factor for both EOAD and LOAD, whereas *APOE*2* is associated with a lower risk, and *APOE*3* a protective effect.[18,22]

Brain Vascular Disease and High Cholesterol

There is growing evidence of a causal association between cardiovascular disease and its risk factors and the incidence of AD. Cardiovascular risk factors that are also risk factors for dementia include hypertension, hypercholesterolemia, and diabetes.[23] For a given amount of AD pathology, vascular disease in the brain may compound the degree of cognitive impairment observed.[19] Vascular disease may accelerate amyloid deposition and reduce clearance of Aβ from the brain.[24] Presence of cardiovascular risk factors in midlife is strongly associated with development of AD in late life.[24] Midlife hypertension is adversely associated with AD, while late life hypertension may be inversely associated. Blood pressure decreases in the years leading up to clinical onset of dementia, conceivably because of reductions in physical activity and body weight.[24]

Mechanistically, the increased risk of AD seen among people with prediabetes and diabetes may be a result of microvascular damage or direct neurotoxicity related to increased glucose and insulin levels.[24] Disturbances in insulin-signaling pathways, both in the periphery and the brain, have been linked to AD. Insulin may also regulate the metabolism of Aβ and tau protein.[25]

Research has found multiple links between cholesterol and AD. Elevated cholesterol levels in brain neurons may alter membrane functioning and result in the cascade leading to plaque formation and AD.

Other Mechanisms

Other hypotheses proposed to explain AD pathogenesis include oxidative stress, mitochondrial dysfunction, and loss of estrogen. Each of these mechanisms may contribute to AD pathogenesis, but the extent of their contribution is uncertain. There is a growing body of evidence regarding the role of oxidative stress and the accumulation of free radicals in the brains of people with AD.[4] Some epidemiologic studies suggest vitamin E, and possibly the combination of vitamin E and vitamin C, may reduce AD risk, while others do not.[26] Mitochondrial dysfunction may result in disruption of energy metabolism in the neuron.[1,15] The role of estrogen in cognitive aging and dementia continues to be an active area of investigation. Despite convincing evidence that estrogens affect the brain in ways that would be expected to improve cognitive aging and reduce the risk of AD, the results of clinical studies have been largely disappointing.[27]

A single common mechanism for developing AD does not exist. Regardless of the etiology, however, the features remain the same: degeneration of neurons in higher brain areas; accumulation of NFTs and amyloid plaques; profound destruction of cholinergic pathways; and an insidious dementia, slowly progressive until death.

CLINICAL PRESENTATION

④ In the absence of abrupt changes in cognition or function, the onset of AD can be almost imperceptible. There are often pathologic changes related to AD long before symptoms emerge, and further deficits occur progressively over time, affecting multiple areas of cognition and function.[3,15] Figure 73-1 depicts the transition from preclinical AD to dementia of the Alzheimer type. Early disease may be characterized by changes in learning and memory, planning and organization, and mood. If these deficits do not impact patient function, the patient may be considered to have MCI. Approximately 15% of patients with MCI will develop dementia after 2 years.[3] Within 5 years, approximately one-third will develop dementia of the Alzheimer's type.[3] Patients with MCI may or may not experience further decline that impairs function and transition to dementia. These patients represent a critical juncture in evaluation, management, and potential mitigation of further cognitive decline.[3]

FIGURE 73-1

The continuum of Alzheimer disease: Progression of pathophysiology and clinical symptoms of AD. If you need more you can add that this figure outlines clinical differences symptomatology in disease progression during the early and late stages of AD, as well as the mechanisms underlying these changes. As pathology progresses, patients may experience further decline in these domains, as well as changes in personality, judgment, speech, and spatial orientation that begin to impact function. In the late stages of dementia, functional decline may be associated with gait changes, swallowing difficulties, and incontinence symptoms; behavioral changes may also result. For treatment and assessment purposes, it is helpful to divide AD symptoms into two basic categories: cognitive symptoms and neuropsychiatric (behavioral) symptoms. Cognitive symptoms are present throughout the illness, whereas behavioral symptoms are less predictable. Table 73-2 and Fig. 73-1 summarize the stages of AD.

TABLE 73-2

Stages of Alzheimer Disease

Mild (MMSE score 26–21)	Patient has difficulty remembering recent events. Ability to manage finances, prepare food, and carry out other household activities declines. May get lost while driving. Begins to withdraw from difficult tasks and to give up hobbies. May deny memory problems.
Moderate (MMSE score 20–10)	Patient requires assistance with activities of daily living. Frequently disoriented with regard to time (date, year, and season). Recall of recent events is severely impaired. May forget some details of past life events and names of family and friends. Functioning may fluctuate from day to day. Patient generally denies problems. May become suspicious or tearful. Loses ability to drive safely. Agitation, paranoia, and delusions are common.
Severe (MMSE score 9–0)	Patient loses ability to speak, walk, and feed self. Incontinent of urine and feces. Requires care 24 hours a day, 7 days a week.

MMSE, Mini-Mental State Examination.

Data from References 5 and 28.

CLINICAL PRESENTATION: Alzheimer Disease

General

- The patient may have vague memory complaints initially, or the patient's friends or family may report that the patient is "forgetful." Cognitive decline is typically gradual over the course of illness. Behavioral disturbances may be present in moderate stages. Loss of daily function such as dressing, bathing, and toileting is common in advanced stages.

Symptoms

Cognitive

- Memory loss (poor recall and losing items)
- Aphasia (circumlocution and anomia)
- Apraxia
- Agnosia
- Disorientation (impaired perception of time and unable to recognize familiar people)
- Impaired executive function

Neuropsychiatric

- Depression, psychotic symptoms (hallucinations and delusions)
- Behavioral disturbances (physical and verbal aggression, motor hyperactivity, uncooperativeness, wandering, repetitive mannerisms and activities, and combativeness)

Functional

- Inability to care for self (dressing, bathing, toileting, and eating)

Diagnosis

According to the 2018 World Alzheimer Report, dementia is often underdetected, underdiagnosed, and subsequently undertreated and undermanaged.[29] Up to 75% of individuals seen in a primary care setting are not given an AD diagnosis.[30] Reasons for this include lack of awareness by patients or their family and friends that the early decline may be associated with AD, or limitations due to clinician awareness, training, and/or time.[30] Despite the phenomenon of underdiagnosis, the US Preventive Services Task Force concluded that there are insufficient data to recommend for or against routine cognitive screening in the absence of symptoms as the benefits may not outweigh the risks, as evidence does not suggest that screening impacts decision making.[30] However, screening for cognitive impairment is a required element of the Medicare Annual Wellness Visit.[31,32] Screening should always occur in the presence of symptoms recognized by the patient, family, or clinician. Discussing the diagnosis of dementia is potentially distressing for patients and their loved ones, especially during initial discussions. Most people, however, prefer to be told about a dementia diagnosis, as it allows them to appropriately plan and access necessary support and treatment services in the meantime.[5]

The Mini-Mental State Examination (MMSE) is a 30-point assessment tool for AD frequently cited in the literature and employed in practice; because of its copyrighted status; however, the MMSE must either be administered from memory or paid for by the user. Similarly, the Montreal Cognitive Assessment became proprietary in 2019, and users must now be trained and certified.[33] Alternatives include the Mini-Cog and the Saint Louis University Mental Status Exam.[34] Each of these tools varies in their characteristics, including sensitivity and specificity, for identifying an underlying dementia.

The only way to confirm a clinical diagnosis of AD is through direct examination of brain tissue at autopsy or biopsy. Several criteria have been used in clinical practice and research for the detection and diagnosis of dementia, including the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*) criteria,[35] the Agency for Healthcare Research and Quality guidelines,[36] the American Academy of Neurology guidelines,[37] the National Institute of Neurological Disorders and Stroke criteria,[38] and the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA) criteria.[39] The *DSM-5* has subsumed the terminology dementia under major neurocognitive disorder; however the term *dementia* is still often used in clinical practice.[35]

In 2011, revisions to the NINCDS-ADRDA criteria for the clinical diagnosis of AD were recommended by the National Institute on Aging (NIA) and the Alzheimer Association (AA).[40] The new NIA-AA criteria view AD as a spectrum beginning with a preclinical phase progressing to increasingly severe clinical stages of AD, as depicted in Fig. 73-1. Three workgroups formulated diagnostic criteria for the dementia phase[41]; the symptomatic, predementia phase (MCI);[42] and the asymptomatic, preclinical phase of AD.[45] The preclinical phase has been further broken down into three stages—stage 1 (asymptomatic cerebral amyloidosis), stage 2 (asymptomatic amyloidosis plus neurodegeneration), and stage 3 (amyloidosis plus neurodegeneration plus subtle cognitive/behavioral decline).[43] In 2018, the American Academy of Neurology updated their practice guideline for MCI.[43,44] Commonalities between guidance documents include the association of impairments in multiple cognitive domains and functional impairment with a clinical diagnosis of AD.

AD remains a primarily a clinical diagnosis, but this will likely change as brain imaging, CSF testing, and other AD biomarkers supporting definitive diagnosis become increasingly available for routine clinical use. The patient's examination should suggest that cognitive decline from a previously higher baseline has occurred. The history should corroborate this finding and further indicate that cognitive decline has reached the point where changes in social or occupational functioning are present. It is possible to administer full neuropsychiatric testing—a battery of sophisticated exams that defines cognitive domain strengths and weaknesses and enables a neuroanatomic localization of the observed deficits. When approached in this way, neuropsychiatric testing can indicate a pattern of cognitive decline that is consistent with AD and assist with rendering a diagnosis that is as much a diagnosis of inclusion as it is of exclusion. Neuropsychiatric testing is considered optional but can prove quite useful for the diagnosis of AD, as well as differentiating types of cognitive impairment.

Objectively defining social or occupational dysfunction can prove tricky in the older patient who may be retired, lead a socially restricted lifestyle, or experience frailty. For such patients, the minimal requirement is to establish a negative impact on day-to-day life. Early on, this usually involves a change in instrumental activities of daily living (eg, handling finances and organizing medications) rather than basic activities of daily living (eg, hygiene and dressing). Some AD subspecialists use a detailed, standardized, semistructured interview of a nonpatient informant such as a caregiver as the most critical piece of the diagnostic evaluation.[45]

⑤ For people who meet criteria for dementia (whether the underlying cause is ultimately suspected to be AD or not), current recommendations from the American Academy of Neurology include a serologic evaluation that includes blood cell counts, serum electrolytes, liver function tests, a test of thyroid function, and a vitamin B_{12} level to rule out other causes of cognitive decline.[37] When circumstances suggest AD is not the leading entity on the differential diagnosis, other neurologic tests such as CSF analysis or electroencephalogram can occasionally be justified.

Guidelines recommend that structural imaging (noncontrast enhanced computed tomography [or CT] or magnetic resonance imaging [MRI]) be performed in the evaluation of people with suspected dementia.[46] These tests may identify structural abnormalities consistent with AD or other pathology, such as brain atrophy, vascular damage, or tumors. Efforts to define the role of other AD diagnostic tests are ongoing.

Use of preclinical indicators typically reserved for the research setting, such as functional imaging, CSF biomarkers, and genetic tests, may become increasingly important with the emergence of potentially disease-modifying agents. Positron emission tomography, or PET, scanning may be used to identify a pattern of neurodegeneration consistent with AD. Such neurodegeneration may be evidenced by reduced uptake of a glucose tracer, indicating hypometabolism, or by modified uptake of an amyloid- or tau- specific tracer, indicating the presence of CNS pathology.[47] Radiologic tracers specific to amyloid plaques (Pittsburgh compound B [PiB], florbetapir F18, florbetaben F18, and flutemetamol F18) often used in research may be used to identify individuals with early disease; however, without widespread access, clinical utility is limited. Additionally, the diagnostic accuracy of PET scanning alone still lags behind that of the clinical examination and history.[43] The presence of amyloid and tau within the CSF may also be utilized to identify patients with early stages of AD, but similar access and interpretation barriers exist.[48] Likewise, *APOE* genotyping is not clinically recommended now, as presence of an _APOE*4_ allele alone does not cause AD.[49] While _APOE_ genotyping by itself is insufficient to make a diagnosis of AD, demonstrating an _APOE*4_ allele in a suspected patient increases the specificity of the diagnosis. Unless the person developed dementia before the age of 60 years and also had a parent who developed AD before the age of 60 years, _PSEN1_, _PSEN2_, or APP genotyping is usually not indicated. Unclear benefits, potential harms, and ethical concerns limit testing for genetic causes of dementia as a part of routine diagnosis and should only be completed with informed consent following genetic counseling.[49]

Mild Cognitive Impairment

Aging is associated with changes in cognitive function. Importantly, MCI constitutes a syndromic designation that categorizes people with cognitive complaints insufficient to warrant a dementia diagnosis. The NIA-AA criteria specifically address the diagnosis of MCI.[42,44,50] Approximately 15% of patients with MCI will develop dementia after 2 years.[3,50] While clinicians may be seeing the initial manifestation of a progressive, degenerative dementia that will eventually meet AD diagnostic criteria, not everyone meeting MCI criteria will develop AD.[42,44] When a diagnosis of MCI is made, routine cognitive screening should be done to monitor for further cognitive loss.

TREATMENT

Desired Outcome

⑥ Approved and investigative pharmacologic therapies have generally failed to demonstrate a reduced risk of progression to dementia, including when used in early MCI.[44,51] As such, the primary goal of treatment in AD is to symptomatically treat cognitive difficulties and preserve patient function for as long as possible. Secondary goals include managing psychiatric and behavioral sequelae. Current AD treatments do not seem to prolong life, cure AD, or halt or reverse the pathophysiologic processes of the disorder.[45]

General Approach to Treatment

Prior to initiating treatment for AD, a thorough medication review should be completed, as almost all can contribute to cognitive impairment in vulnerable individuals, but certain classes are more commonly implicated. Benzodiazepines and other sedative hypnotics, anticholinergics, and antipsychotics have been associated with cognitive impairment.[52] In addition, H_2-receptor antagonists, corticosteroids, and opioids like meperidine have been implicated in cases of delirium or acute cognitive change.[52] Because medication use is a reversible cause of cognitive symptomatology, medication review and management are essential.

Clinical trials have consistently modest benefits of early and continuous treatment with cholinesterase inhibitors with the addition of memantine in moderate-to-severe disease.[53] Following this approach allows for maximal maintenance of cognition and activities of daily living, along with a symptomatic approach being used to address behavioral symptoms as they arise. Considering the Food and Drug Administration (FDA) approval of potentially disease-modifying immunotherapies for use in MCI and early AD, it remains to be seen how the place in therapy of cholinesterase inhibitors and/or memantine will change, if at all. Patient and family education at the time of diagnosis, including discussion of the course of illness, realistic expectations of treatment, and the importance of legal and financial planning are essential to appropriate treatment.

Recommendations for patients with renal or hepatic dysfunction or low body weight are detailed in Table 73-3. It is important to consider that most people with AD are older adults and therefore may be taking multiple medications for other acute and chronic health conditions.[54] The benefits of medication therapy for AD and other comorbid medical conditions must be weighed against each medication's time-to-benefit and potential for adverse events.

TABLE 73-3

Dosing of Medications Used for Cognitive Symptoms

Medication	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other

Cholinesterase Inhibitors					
Donepezil	Aricept, Aricept ODT	5 mg daily in the evening	• 5-10 mg daily in mild-to-moderate AD • 10-23 mg daily in moderate-to-severe AD	No dosage adjustments recommended	• Available as: tablet, ODT, oral solution • Can be taken with or without food • Incidence of GI adverse effects (incudling weight loss) are higher with 23-mg daily dose • Therapy interruptions require retitration of dose
Rivastigmine	Exelon, Exelon Patch	• 1.5 mg twice daily (capsule, oral solution) • 4.6 mg/day (transdermal patch)	• 3-6 mg twice a day (capsule, oral solution) • 9.5-13.3 mg/day (transdermal patch)	• Capsule/oral solution: Renal impairment, hepatic impairment, or low body weight (<50 kg [<110 lb]): may be able to only tolerate lower doses • Transdermal patch: Mild-to-moderate hepatic impairment or low body weight: consider maximum daily dose of 4.6 mg every 24 hours	• Available as: capsule, oral solution, transdermal patch • Therapy interruptions require retitration of dose • Take with meals • Also indicated for mild-to-moderate dementia associated with Parkinson disease • Use of multiple transdermal patches at same time associated with hospitalization and death
Galantamine	Razadyne, Razadyne ER	• 4 mg twice daily (tablet, oral solution) • 8 mg daily in the morning (extended-release capsule)	• 8-12 mg twice a day (tablet, oral solution) • 16-24 mg (extended-release capsule)	• Moderate renal or hepatic impairment: maximum daily dose of 16 mg • Severe renal or hepatic impairment: not recommended	• Available as: tablet, oral solution, extended-release capsule • Recommended to take with meals
***N*-methyl-D-aspartate (NMDA) Receptor Antagonist**					
Memantine	Namenda, Namenda	• 5 mg daily (tablet, oral solution)	• 10 mg twice daily	• Severe renal impairment: recommended maintenance dose	• Available as: tablet, oral solution,

	XR	- 7 mg daily (extended-release capsule)	- 28 mg daily (extended-release capsule)	of 5 mg twice daily (tablet, oral solution) or 14 mg daily (extended-release capsule) - Severe hepatic impairment: administer with caution	extended-release capsule - Therapy interruptions require retitration of dose - Can be taken with or without food Can open capsule and sprinkle contents on applesauce for ease of administration
Cholinesterase Inhibitor + NMDA Receptor Antagonist					
Memantine + Donepezil	Namzaric	- 7 mg/10 mg daily (if patient is stabilized on donepezil and not currently on memantine) - 28 mg/10 mg daily (if patient is stabilized on memantine and donepezil)	28 mg/10 mg daily	Severe renal impairment: 14 mg/10 mg daily	- Available as: memantine extended-release and donepezil capsule - Can be taken with or without food - Can open capsule and sprinkle contents on applesauce for ease of administration
Anti-amyloid Monoclonal Antibody					
Aducanumab-avwa	Aduhelm	1 mg/kg intravenous	Titrated up to 10 mg/kg intravenous once every 4 weeks	No dosage adjustments recommended	- Available as 170 mg/1.7 mL and 300 mg/3 mL single-dose vials - Must be diluted in 100 mL of 0.9% NaCl and administered over ~ 1 hour

[a] In cases of insomnia or vivid dreams, may dose in the morning. ODT, orally disintegrating tablet.

Data from References 55–63.

Nonpharmacologic Therapy

⑦ Evidence has been insufficient to warrant the routine use of non-pharmacologic interventions to prevent or delay the development of dementia or AD. There has been promising evidence; however, that promotion of a healthy lifestyle in mid-life may help modify potential risk factors for LOAD.[64-68] A 2018 meta-analysis found exercise training may delay cognitive decline in persons at risk for AD.[68] Specifically the World Health Organization recommends weekly moderate-intensity aerobic exercise (at least 150 minutes) to help preserve functioning and reduce risk.[68]

AD has a profound effect on both the patient and family. Use of nonpharmacologic interventions is the current primary strategy for management of AD, and medications should be used in the context of multimodal interventions. Neuropsychiatric symptoms (also referred to as behavioral and psychological symptoms of dementia [BPSD]) are among the most challenging and distressing symptoms of the disease and may be the determining factor in a family's decision to seek institutional care. Symptoms such as sleep disturbances, wandering, urinary incontinence, agitation, and aggression in patients with dementia are best managed using behavioral interventions rather than medications whenever possible.[53,69]

Upon initial diagnosis, the patient and caregiver should be educated on the course of illness, prognosis, available treatments, legal decisions, and quality of life issues. Caregiving strategies, including stress-management techniques and support group options, should also be discussed. Caregiver education and support programs improve caregiver skill, knowledge, confidence, and quality of life, and even delay time to nursing home placement for their loved one.[70,71] Table 73-4 lists basic principles of care for people with AD.

TABLE 73-4

Basic Principles of Care for the Person with Alzheimer Disease

1. Consider vision, hearing, or other sensory impairments
2. Find optimal level of autonomy and adjust expectations for patient performance over time
3. Avoid confrontation. Remain calm, firm, and supportive if the patient becomes upset. Validate their feelings
4. Maintain a consistent, structured environment with stimulation level appropriate to the individual patient
5. Provide frequent reminders, explanations, and orientation cues; employ guiding, demonstration, and reinforcement
6. Reduce choices, keep requests and demands of the patient simple, and avoid complex tasks that lead to frustration
7. Bring sudden declines in function and the emergence of new symptoms to professional attention
8. Redirect to an enjoyable activity

Data from References 2,49,72,73.

The general approach to nonpharmacologic strategies for BPSD is to identify the symptom, determine causative factors, and adapt the caregiving environment to remedy the situation.[3] Environmental triggers may include noise, glare, and too much background distraction, including television. Personal discomfort may also trigger behaviors, so it is important to monitor for pain, hunger, thirst, constipation, full bladder, fatigue, infections, skin irritation, personal care, comfortable temperature, fears, and frustrations.[69,71,73] Medical comorbidity is a major source of functional and cognitive impairment in people with AD, so general health maintenance is necessary.[3] Interventions should redirect the patient's attention rather than be confrontational and should specifically address known triggers. Creating a calm environment and removing stressors and triggers is key. Other nonpharmacologic approaches include exercise, light therapy, music therapy, reminiscence therapy, aroma therapy, relaxation techniques, validation therapy, massage and touch therapy, and multisensory stimulation.[71,73] Caregivers should be referred to support services for assistance in developing nonpharmacologic strategies for managing difficult behaviors.

The caregiver must be prepared to face the changes in life that will occur, and acceptance rarely comes easily. Denial on the part of the patient and rationalization on the part of the family are common. The clinician should encourage the family to address legal and financial matters and designate a durable power of attorney for execution of financial and medical decisions once the patient can no longer make those decisions or is deemed incompetent. The caregiver will need to identify resources to provide respite services as they will need time for rest, relaxation, and the conduct of personal business. Eventually, they will need to face critical and difficult questions with respect to institutionalization. Local and national resources, such as the AA, can provide detailed information regarding support services. Table 73-5 lists this and other referral sources for caregivers. Education, communication, and planning are key nonpharmacologic components of caring for a person with AD. Preparation in the early stages of illness may lessen some caregiver stress as the disease progresses.

Pharmacologic Therapy

Pharmacotherapy for Cognitive Symptoms

⑧ Table 73-6 presents pharmacologic treatment recommendations for managing cognitive symptoms in AD. Current guidelines recommend initiation of cholinesterase inhibitors for AD with no preference for a specific agent.[53,74] Galantamine and oral rivastigmine are FDA approved in mild-to-moderate AD. Donepezil and transdermal rivastigmine are FDA approved in mild, moderate, and severe disease. Despite inconclusive evidence for early intervention, cholinesterase inhibitors are commonly prescribed off-label prior to formal diagnosis of AD. Memantine is indicated for moderate-to-severe AD, as current evidence does not support its use in earlier disease stages.[53,74] Additional benefit may be achieved when memantine is added to cholinesterase inhibitor therapy in moderate-to-severe AD; however, the data is conflicting.[53,74] There is no evidence supporting combination therapy of more than one cholinesterase inhibitor. Cholinesterase inhibitors have not demonstrated efficacy for use in MCI.[44,51] At present, anti-amyloid monoclonal antibodies are the only drug class indicated for use in patients with MCI due to AD.[59.60]

TABLE 73-6

Pharmacologic Treatment Options for Cognitive Symptoms in Alzheimer Disease

- In MCI due to AD, consider therapy with an anti-amyloid mAb (aducanumab), then titrate to recommended maintenance dose as tolerated
- In mild-to-moderate AD, consider therapy with a cholinesterase inhibitor (donepezil, rivastigmine or galantamine) or aducanumab then titrate to recommended maintenance dose as tolerated
- In moderate-to-severe AD, consider adding antiglutamatergic therapy (memantine); then titrate to recommended maintenance dose as tolerated; alternatively, consider memantine or cholinesterase inhibitor therapy alone
- Behavioral symptoms may require additional pharmacologic approaches

Data from Reference 74.

Cholinesterase Inhibitors

⑧ In the early 1980s, researchers began to examine means to enhance cholinergic activity in people with AD by inhibiting the hydrolysis of acetylcholine through reversible cholinesterase inhibition. Tacrine was the first such medication to be examined in a systematic fashion and is no longer available in the US market, having been replaced by safer, more tolerable cholinesterase inhibitors. The newer cholinesterase inhibitors donepezil, rivastigmine, and galantamine show similar modest symptomatic improvements in cognitive, global, and functional outcomes in people with mild-to-moderate AD, and duration of benefit varies from 3 to 24 months.[75,76] One open-label extension study of galantamine showed benefit beyond the 24-month mark.[77]

The mechanism of action differs slightly between medications in this class.[78] Donepezil specifically and reversibly inhibits acetylcholinesterase. Rivastigmine is a pseudo-irreversible inhibitor of both butyrylcholinesterase (an "overflow" enzyme to acetylcholinesterase) and acetylcholinesterase. Galantamine is a selective, competitive, reversible acetylcholinesterase inhibitor that also enhances the action of acetylcholine on nicotinic receptors. The clinical relevance of these differences is unknown.

Choice of cholinesterase inhibitor therapy for an individual patient is based primarily on ease of use, patient preference, cost, and safety issues, such as potential for interactions. Pharmacokinetic properties should also be considered, as rivastigmine and galantamine have short half-lives (1.5 and 7 hours, respectively) compared to donepezil (70 hours). If rivastigmine or galantamine treatment is interrupted for several days or longer, the patient should be restarted at the lowest dose and titrated up to the current dose. This is true for all formulations of cholinesterase inhibitors, including the rivastigmine transdermal patch.[55-57] Dosing strategies for cholinesterase inhibitors and memantine are summarized in Table 73-3.

Adverse medication reactions and corresponding monitoring parameters are described in Table 73-7. Cholinesterase inhibitors have similar, pro-cholinergic adverse reaction profiles, and are generally well tolerated. The most frequent adverse reactions associated with these agents are mild-to-moderate gastrointestinal (GI) symptoms (eg, nausea, vomiting, and diarrhea) that may impact appetite and weight.[79] Gradual dose titration over several weeks to months can improve tolerability.[34] Alternatives to the immediate-release dosage form are available for patients who have complex dosing regimens, tolerability issues, or difficulty swallowing, though cost may be an issue. Bradycardia has been noted to be a potentially dose-limiting adverse effect for the class and use is contraindicated in patients with a heart rate below 50 beats per minute. When this is a concern, consideration should be given to reducing other heart rate limiting medications (eg, beta-blockers) where appropriate. In patients who report pro-cholinergic increases in urinary frequency, concurrent use of anticholinergic medications with cholinesterase inhibitors should be avoided and nonpharmacologic interventions employed, if possible.[80] Patients and caregivers should be cautioned against abrupt discontinuation of cholinesterase inhibitor therapy, as this can lead to worsening cognition and behavior in some people with AD.[81] Cholinesterase inhibitors may have some potential to cause seizures; however, they may also be related to AD.[55-57]

TABLE 73-7

Monitoring Medication Therapy for Cognitive Symptoms

Medication	Adverse Medication Reaction	Monitoring Parameter	Comments
Cholinesterase inhibitors	Dizziness, syncope, bradycardia, atrial arrhythmias, sinoatrial and atrioventricular block, myocardial infarction	Report of dizziness or falls, pulse, blood pressure, and postural blood pressure change	• Dizziness is usually mild, transient, and not related to cardiovascular problems • Routine pulse checks at baseline, monthly during titration, and every 6 months thereafter
	Nausea, vomiting, diarrhea, anorexia, weight loss	Weight and GI complaints	• Take with food to decrease GI upset • Usually transient, dose-related GI adverse effects seen with medication initiation, dosage titration, or medication switch • Frail patients or those with low body weight may be more likely to experience GI adverse effects and significant weight loss, particularly when rivastigmine is prescribed or when titrating to donepezil 23 mg • GI adverse effects less prominent with transdermal versus oral rivastigmine

	Peptic ulcer disease, GI bleeding	Signs or symptoms of active or occult GI bleeding	Of particular concern for patients at increased risk of developing ulcers, such as those with a history of ulcer disease or concurrently taking NSAIDs
	Insomnia, vivid/abnormal dreams, nightmares	Complaints of sleep disturbances, daytime drowsiness	Donepezil can be taken in the morning to decrease risk of sleep disturbances
Galantamine	Serious skin reactions (Stevens-Johnson syndrome and acute generalized exanthematous pustulosis)	Appearance of skin rash	• Discontinue galantamine at first sign of skin rash, unless clearly not medication related • If signs/symptoms are suggestive of a serious reaction, consider alternative treatment and do not rechallenge
Rivastigmine	Allergic dermatitis	Application site reaction spread beyond patch size, evidence of a more intense local reaction (increasing erythema, edema, papules, vesicles), and persistence of symptoms for more than 48 hours after patch removal	• Discontinue rivastigmine if evidence of disseminated allergic dermatitis appears • Patients sensitized by exposure to the transdermal patch may not be able to take rivastigmine by mouth either; allergy testing and close medical supervision recommended
Memantine	Headache, confusion, dizziness, hallucinations	Report of dizziness or falls, hallucinations	Confusion may be observed during dose titration and is usually transient
	Constipation	GI complaints	Memantine may mitigate GI adverse effects associated with cholinesterase inhibitor therapy
Aducanumab	Amyloid-related imaging abnormalities (ARIA)	• MRI at baseline, prior to 7th and 12th infusions or if a patient experiences symptoms suggestive of ARIA to identify brain edema, microhemorrhage, superficial siderosis • Symptoms of headache, confusion, dizziness, visual disturbances, and nausea	Vigilance for ARIA and focal neurologic changes are recommended during dose titration and the first 8 doses
	Hypersensitivity reactions	Angioedema and urticaria (rare)	

ARIA, amyloid-related imaging abnormalities; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

Data from References 53,55–57,61,62,82.

The use of high-dose donepezil (23 mg) may be associated with an improvement in cognitive measures; however, some may consider this clinically insignificant.[82] Additionally, this dose is associated with a threefold increased risk of GI effects and a near doubling in the rate of treatment withdrawal, leading to it not being routinely prescribed in clinical practice.

Depending on individual patient response, tolerability, and preference, switching to an alternate dosage form or alternative cholinesterase inhibitor may be necessary during the course of AD treatment. Manufacturer recommendations for this practice are specified in the prescribing information, but the optimal procedure for switching between agents remains uncertain. When switching from one cholinesterase inhibitor to another due to intolerance, a washout period is recommended. Length of the washout period may vary based on pharmacokinetics and time to adverse reaction resolution.[83] Some patients who fail to respond to donepezil, rivastigmine, or galantamine may respond when switched to a different medication with some clinicians preferring an overnight switch to minimize the potential for clinical deterioration.[83] Importantly, loss of benefit over time may not be an appropriate reason to switch cholinesterase inhibitors, as the progressive nature of AD is likely to become more noticeable over time.[83] Indeed, initiation of memantine may be a more appropriate next step as patients progress in their disease course.[49]

In natural disease progression studies, scores on the Alzheimer's Disease Assessment Scale—Cognitive Subscale (ADAS-cog) worsen (increase) by an average of five or fewer points over 1 year in mild dementia and 7 to 11 points annually in moderate dementia. Based on these findings, the consensus is that a four-point change in the ADAS-cog represents a clinically significant change.[53] Therefore, if a pharmacotherapeutic agent improves (decreases) the ADAS-cog score by four points, one could think of this as having delayed progression of disease symptoms by 6 months. The usefulness of the ADAS-cog in clinical practice is limited because of the administration time. Therefore, it is much more practical to assess changes in disease severity using the MMSE or other assessment tools. An untreated person with AD has an average decline of two to four points in MMSE score per year. Successful treatment would reflect a decline of less than two points a year. It is reasonable to change to a different cholinesterase inhibitor if the decline in MMSE score is greater than two to four points after 1 year with the initial agent.[83]

Antiglutamatergic Therapy

(8) Memantine is the only NMDA receptor antagonist available for AD. Glutamate is an excitatory neurotransmitter in the brain implicated in long-term potentiation, a neuronal mechanism important for learning and memory.[49] Blocking NMDA receptors can mitigate excitotoxic neurotoxicity and potentially provide neuroprotection (as has been suggested in animal models); however, there is no clinical evidence to indicate that memantine confers neuroprotection in AD.[84]

Memantine is indicated for use in moderate-to-severe AD.[61] Its use has been studied in people with moderate and severe AD as monotherapy and in combination with donepezil with favorable results on cognition and function.[74] To date, studies of memantine alone and in combination with cholinesterase inhibitors in mild AD have provided insufficient evidence to support an indication for mild AD.[74]

In tablet or oral solution form, memantine should be initiated at 5 mg once a day and titrated weekly in 5 mg intervals to the target maintenance dose of 10 mg twice daily. The extended-release capsule form of memantine is to be initiated at 7 mg daily and titrated weekly up to a maximum of 28 mg daily. Dose titration is achieved in 7 mg intervals with at least 1 week between dose adjustments. Dosing of 5 mg twice daily (tablet and oral solution) or 14 mg daily (extended-release capsule) is recommended in patients with severe renal impairment (creatinine clearance of 5-29 mL/min [0.08-0.49 mL/s]).[61,62]

Memantine has been well tolerated in randomized clinical trials (RCTs). Common adverse events include headache, constipation, confusion, and dizziness. Post-marketing cases of treatment emergent agitation have been reported as well. It has 100% bioavailability regardless of administration with or without food and protein binding is relatively low (45%). Memantine is not metabolized by the liver, does not inhibit cytochrome P450 activity, and is primarily excreted unchanged in the urine with a half-life of 60 to 80 hours.[61,62]

Role of Combination Therapy

Combination therapy with memantine added to a cholinesterase inhibitor is generally prescribed for people with moderate-to-severe AD, as the medication classes have different mechanisms of action. This practice slows cognitive and functional decline to a significant degree compared to cholinesterase inhibitor monotherapy or no treatment.[85] One trial randomized people with moderate-to-severe AD already receiving stable donepezil treatment to either memantine or placebo. At the end of 6 months, participants randomized to receive memantine and donepezil had significantly better outcomes in measures of cognition, function, behavior, and global status than those continued on donepezil monotherapy. This group also had a lower rate of discontinuation due to adverse events.[86] Based on data from this study and others, memantine may have a role in mitigating GI adverse events associated with cholinesterase inhibitors.

In 2014, a combination product containing memantine extended-release and donepezil was approved by the FDA for moderate-to-severe AD in patients already stabilized on memantine and donepezil.[63] As medication effectiveness was based on bioequivalence with the two active ingredients, the package insert separately lists the most common adverse effects of each and not in combination. This product comes in four fixed dose strengths, and dosage reduction is recommended in the case of severe renal impairment. No dosage adjustments are needed in patients with mild or moderate renal or hepatic impairment and it has not been studied in patients with severe hepatic impairment.

Anti-amyloid Monoclonal Antibody

Disease-modifying immunotherapies have long been of interest in pharmacotherapy development; however, both active and passive immunotherapies against amyloid have historically failed to modify disease course. Additionally, they have resulted in serious adverse events, including brain edema and meningitis, thought to be related to transient increases in vascular amyloid secondary to the clearance and removal of vascular amyloid resulting in cerebral edema or microhemorrhage.[18,19,87,88] Hypothetically, agent selectivity and early disease course intervention may optimize success and mitigate such adverse events. The available and investigational agents vary in their mechanism (active vs passive), amyloid target (eg, more pathological oligomeric vs potentially protective monomeric amyloid, soluble vs insoluble amyloid, amyloid amino acid residue) and binding conformations.[87-91] Although active immunotherapies remain in development, passive immunotherapies have been a large part of the pipeline owing to their ability to provide a more predictable and controlled response.

Four humanized, immunoglobulin G1 monoclonal antibodies have been designated as AD breakthrough therapies by the FDA (ie, aducanumab, lecanemab, donanemab, and gantenerumab), where preliminary evidence indicates substantial improvement over existing therapies on significant endpoints.[92-95] One of these agents, aducanumab, was controversially approved under this accelerated pathway for use in MCI due to AD and mild AD. Three phase III trials evaluated the safety and efficacy of aducanumab in this population. While all three trials had reductions in biomarker-indicated pathology such as presence of amyloid or tau in a dose and time-dependent manner, two trials were ended early for presumed clinical futility. A later re-analysis of the data found a significant reduction in cognitive, functional, and behavioral decline in only one trial. Under the accelerated pathway, continued approval of aducanumab is likely to be contingent upon verification of clinical benefit in confirmatory trials underway.[92,93] Phase III trials of donanemab, lecanemab, and gantenerumab are ongoing.[96]

Aducanumab binds to aggregated forms of amyloid in the brain, including oligomer and fibril formations and is reported to preferentially bind perivascular amyloid, which has been hypothesized to reduce the likelihood of cerebral edema or microhemorrhage. It is administered as an infusion delivered every 4 weeks which is titrated to a maintenance dose of 10 mg/kg to reduce the likelihood of CNS adverse effects. It is broken down via endogenous pathways to yield a half-life of approximately 25 days, reaching steady-state before the fifth dose.[59,60]

In addition to infusion-related reactions such as urticaria and angioedema, aducanumab may cause cerebral edema and microhemorrhage. Such CNS-related adverse effects may result in further cognitive decline, focal neurologic changes, and a theoretical increase in risk of intracranial hemorrhage.[59,60] Carriers of *APOE*4* may be at greater risk for these CNS effects owing to a greater burden of vascular amyloid.[97] Screening for baseline cerebrovascular risk and frequent imaging can mitigate these CNS-related effects. Patients at risk for CNS adverse events include those taking anticoagulants and those with underlying cerebrovascular disease. Baseline and monitoring MRI should be conducted to identify patients at risk for these adverse effects, and the development of amyloid-related imaging abnormalities (ARIA) that evidence cerebral edema (ARIA-e) and microhemorrhage (ARIA-h) (see Table 73-7) with treatment. If severe ARIA-h is identified, patients may continue treatment if clinical evaluation and MRI imaging demonstrate stabilization; otherwise therapy should be discontinued. Patients should also be monitored for the development of focal neurologic symptoms. Patients with uncontrolled seizure disorder should be excluded from treatment due to the risk of focal neurologic adverse events.[59,60]

The potential degree and duration of clinical benefit of anti-amyloid antibodies remains largely unclear. The unknown durability of effect and adverse effect profile, combined with the possible decline in self-management capacity to meet the administration and monitoring requirements, render their place in therapy questionable. It is largely unknown what impact therapeutic discontinuation will have on overall progression. In addition, there are access gaps related to reimbursement for medication and ancillary services, as well as the health system resources needed to safely administer and monitor medication use.[98,99] As a result, the Institute for Clinical and Economic review has rated the comparable cost effectiveness of this medication as “insufficient” to demonstrate a net health benefit for patients with MCI due to AD or mild AD.[98]

Effect of Current Treatments on Neurodegenerative Processes

AD is a progressive disorder and affected individuals typically experience some degree of cognitive decline and histologic change for years (if not decades) before a diagnosis is made. Therefore, the ideal treatment will be one that not only reverses symptoms by enhancing cognitive function (a symptomatic treatment) but also arrests the neurodegeneration-relevant molecular processes that underlie cognitive decline (a disease-modifying treatment).

Clinical trials for AD prompt consideration of whether positive outcomes suggest either a symptomatic or disease-modifying effect. Any rapid performance improvement in cognitive ability, activities of daily living, or behavioral end points is indicative of a symptomatic effect. All cholinesterase inhibitor agents and memantine demonstrate this pattern, and aducanumab suggests a similar effect. Arrest of decline or a sustained reduction in the slope of decline would argue the presence of a disease-modifying effect; however, it has not been possible to unequivocally demonstrate this in trials of the approved treatments. Long-duration, double-blind, placebo-controlled trials to evaluate whether available agents have disease-modifying effects are difficult to perform, because doing so would require continuing a placebo arm over an extended period, well beyond demonstration of symptomatic benefit. Also, subject attrition over an extended study would complicate both intent-to-treat and observed case analyses.

With cholinesterase inhibitors and memantine, pivotal placebo-controlled trials were followed by open-label extension studies, lasting as long as 5 years. As part of these studies, decline in the treatment group was compared with "projected" placebo groups based on continued follow up of the placebo groups included in the 6-month randomized phase of the efficacy study, as well as natural history cohorts from the pre-cholinesterase inhibitor therapy era. Although analyses of this sort conclude that, for up to at least 5 years, people receiving treatment exceed their projected nontreatment cognitive performance, no convincing evidence of a disease-modifying effect emerges.[100-103]

Barriers to Clinical Effectiveness Research

Disagreement exists about how best to determine effectiveness of AD treatments. Selection of qualitative versus quantitative assessment may bias a clinician's impression of response as subtle changes are often detected only by psychometric testing. As no standard has been suggested to define the effectiveness of AD medications, great variation exists between clinicians, and the duration of treatment. Realistic expectations for success may include slowed decline in behavioral, functional, and cognitive abilities and delayed long-term care placement.[104] An initial dramatic improvement in symptoms is unlikely but may be reported by a minority of patients or their caregivers.

Unfortunately, clinical trials have failed to provide answers to key questions in treating people with AD and challenges associated with population heterogeneity and difficulties inherent to the diagnosis, make interpretation of therapeutic response difficult.[105] For example, individuals given a diagnosis for AD often lack the hallmark pathologies (ie, amyloid plaques and NFTs) on postmortem examination. Similarly, clinical trials of potentially disease modifying agents have failed to produce reliable results, indicating that disease stage and preclinical diagnosis may be of increasing importance. Additionally, because of overlap between AD and other dementing illness, trials including those diagnosed with AD may in fact include patients with a heterogenous, mixed profile of dementia. Further, as individuals who fail to display the clinical symptoms of the disease may still be developing the underlying pathologies, there may be contamination of control groups. Each of these factors may present a challenge to the internal validity of clinical trials.

Guidance in extrapolating data related to changes in cognition is needed so a reasonable duration of clinical treatment with pharmacotherapy can be determined. One concern is that those who respond to treatment may lose the benefits of that treatment once the medication is stopped.[106] Gaps in treatment have been linked with worse cognitive outcomes in clinical trial extension studies; however, there is no increased risk of institutionalization or death associated with gaps in cholinesterase inhibitor therapy.[107,108] Regardless, dosing regimens should be simplified and patient and caregiver preferences considered in an effort to improve medication adherence and persistence.

Management of Brain Vascular Health

⑨ Guidelines for the care of people with AD support the management of vascular brain disease and its associated risk factors as part of treatment.[49] There is a link between AD and cardiovascular disease, including heart failure, atrial fibrillation, and coronary artery disease, and a growing body of evidence that brain vascular disease plays a role in the progression of dementia.[21] Management of brain vascular disease includes monitoring blood pressure, glucose, and cholesterol, and initiation of appropriate interventions.[109-111]

The World Health Organization (WHO) and Alzheimer's Disease International encourage primary prevention through public health campaigns targeting smoking, underactivity, midlife obesity, midlife hypertension, and diabetes.[112] Adherence to the Mediterranean Diet, Dietary Approaches to Stop Hypertension (DASH) diet, or combination Mediterranean-DASH Intervention for Neurodegenerative Delay (MIND) diet may reduce the risk of cognitive impairment or decline.[24,113] Physical activity is an important component of vascular brain health and is associated with a reduced risk of cognitive impairment.[24,68,114] However, most positive trial findings have been from cognitively healthy older adults.[24,113] While appropriate management of vascular disease risk factors may reduce the risk for developing AD, insufficient evidence exists to draw definitive conclusions on the association between risk factor modification and risk of AD.[24,109]

Other Potential Treatment Approaches

Estrogen

Estrogen replacement has been studied extensively for the treatment and prevention for AD with most, but not all, retrospective epidemiologic studies showing a lower incidence of AD with estrogen replacement therapy after menopause. Prospective clinical trials have not supported the use of estrogen as a treatment for cognitive decline, and longer trials tend to suggest harm. The evidence does not support the use of estrogen to treat or prevent dementia.[27] Although phytoestrogens found in soy-containing foods and soy-derived dietary supplements have been suggested for the treatment or prevention of dementia, there are no clinical trials supporting such use.[27]

Anti-inflammatory Agents

Retrospective epidemiologic studies suggest a protective effect against AD in patients who have taken nonsteroidal anti-inflammatory drugs (NSAIDs); however, the benefits of anti-inflammatory agents have been less compelling in prospective clinical studies. In fact, there is no significant cognitive benefit in persons with AD treated with NSAIDs, aspirin, or steroids.[115] Due to lack of compelling data and a significant incidence of adverse effects, particularly gastritis and the possibility of GI bleeds, these agents are not recommended for general use in the treatment or prevention of AD.[115]

Lipid-Lowering Agents

Four RCTs of statin therapy, given to older individuals at risk for vascular disease, indicated no significant benefit of statin therapy for probable or possible AD.[116] Cognitive impairment has been recognized as a rare adverse event associated with statin therapy.[117] More research is needed to understand the complex relationship between cholesterol, statin therapy, and cognitive functioning but for now, these agents should be reserved for patients who have other indications for their use.

Dietary Supplements

Many nutraceuticals, herbal products, medical foods, and other dietary supplements have been promoted for the prevention and treatment of AD, and available evidence has been reviewed.[118-120] While a detailed discussion of their use is beyond the scope of this chapter, the more commonly used supplements are as follows.

Vitamin E Supplementation

Based on pathophysiologic theories involving oxidative stress and the accumulation of free radicals in AD, significant interest has evolved regarding the use of antioxidants in the treatment of AD. Two RCTs have evaluated the effects of vitamin E supplementation (1,000 IU twice daily) in people with AD. The first studied people with moderate AD for 2 years and had a significant delay in the time to institutionalization in the treatment group compared to placebo.[121] The second studied the efficacy of α-tocopherol, memantine, or their combination in people with mild-to-moderate AD taking an acetylcholinesterase inhibitor (mean follow-up time of 2.3 years) and showed a reduced annual rate of decline in activities of daily living in those treated with vitamin E, but no cognitive benefits were seen.[122] No significant adverse effects were reported between treatment groups in either study; however, according to a meta-analysis high-dose vitamin E increases mortality.[123] In addition, vitamin E had no benefit in people with MCI in the progression to AD,[124] or in preventing dementia in asymptomatic older males.[125] Considering these findings, there is insufficient evidence to recommend vitamin E supplementation for the treatment or prevention of AD.[126]

Vitamin B Supplementation

Elevated serum homocysteine is associated with cognitive decline and supplementation with B vitamins (folic acid along with B_{12} and/or B_6) has been explored to reduce homocysteine levels in older adults with dementia. Clinical trials consistently demonstrate reduced homocysteine levels in the intervention groups receiving vitamin B supplementation, but without significant difference in MMSE scores between control and intervention groups. In other words, reduced homocysteine levels have not translated into improved cognitive outcomes for people with AD thus far.[127]

Ginkgo biloba

Ginkgo biloba for the prevention and treatment of AD has been extensively studied given its potential to increase blood flow, decrease blood viscosity, antagonize platelet-activating factor receptors, increase anoxia tolerance, inhibit monoamine oxidase, and serve as an antioxidant. Active ingredients in *Ginkgo biloba* include flavonoids, *Ginkgo* flavone glycosides, and bioflavonoids. Most studies reporting benefit in people with cognitive impairment or dementia have studied a standardized extract, EGb 761, in doses of 240 mg/day for 22 to 26 weeks.[128] The clinical significance of the modest benefits detected is unclear, and direct comparisons to cholinesterase inhibitors or memantine are lacking. A large trial of *Ginkgo biloba* 120 mg twice a day did not reduce the overall incidence rate of either dementia or AD in older adults with normal cognition or MCI.[129] In another large trial the long-term use of *Ginkgo biloba* extract did not reduce the risk of progression to AD among older adults suffering from memory complaints compared with placebo.[130] Adverse medication effects reported from EGb 761 studies were typically mild, including nausea, vomiting, diarrhea, headaches, dizziness, palpitations, restlessness, and weakness. Because EGb also has a potent antiplatelet effect, it should be avoided by individuals taking anticoagulant or antiplatelet therapies and should be used cautiously in patients taking NSAIDs.[128,131]

Apoaequorin

Prevagen (apoaequorin) has been postulated to impact cognition by modulating calcium homeostasis and secondary messaging; however, the manufacturer data has not been peer reviewed and only focuses on single domains of cognition. Additionally, a simulation of the gastric environment found that 90% of this compound is broken down within 30 seconds. As the compound is large in size, it is not clear whether there is a mechanism for absorption or ability to cross the blood brain barrier.[132]

Medical Foods

Several medical foods have been studied for the treatment of MCI or AD, but there is little evidence of benefit to date. Medical foods constitute a unique category that consists of ingestible entities intended for the treatment of diseases that have “specific nutritional requirements” and for which the medical food may manipulate disease-relevant pathophysiology. Medical foods are intended to be used under the supervision of a physician. The most commonly used for people with mild-to-moderate AD are Axona, Souvenaid, and CerefolinNAC.[133]

Axona (caprylidene) is a mixture of medium-chain fatty acids, consisting primarily of the C8 fatty acid caprylic acid.[134] Caprylidene is converted by the liver to a ketone body, β-hydroxybutyrate, which crosses the blood–brain barrier and can be used as an alternative fuel to glucose in the brain. Support for caprylidene efficacy in AD comes from a single clinical trial in which subjects randomized to 40 mg/day of caprylidene for 45 days performed relatively better on the ADAS-cog than did subjects randomized to a placebo; however, this benefit was entirely driven by subjects without the *APOE*4* allele.[135] In general, adverse effects were mild, with GI-related effects being the most common. Coconut oil is a source of caprylic acid but may not contain sufficient quantities to meet the needs of a person with AD; however, it continues to be used by some patients as a less expensive alternative to caprylidene.[134]

Souvenaid is a mixture of omega-3 fatty acids (eicosapentaenoic and docosahexaenoic acids), uridine monophosphate, phospholipids, B complex vitamins (B_6, B_{12}, and folate), choline, vitamin E, and selenium.[136] A systematic review and meta-analysis of three RCTs comparing Souvenaid to placebo found no significant differences in cognition, function, or behavior, although one study showed improvement in verbal recall in people with mild AD in the Souvenaid treatment group.[136] No serious adverse events were reported in the clinical studies.

CerefolinNAC contains vitamin B_{12}, L-methylfolate, and N-acetylcysteine, and its use targets the association of hyperhomocysteinemia with MCI and progression to dementia. A small prospective case-control study of people with AD and hyperhomocysteinemia suggested longer CerefolinNAC treatment duration, milder baseline severity, and greater magnitude of homocysteine reduction from baseline were all significant predictors of slowed cognitive decline, when compared to AD subjects with normal homocysteine levels not receiving CerefolinNAC.[137] Randomized controlled trials are needed to confirm these findings; however to date, there is insufficient evidence to recommend medical foods for the treatment of AD.

Omega-3 Fatty Acids

Arguments that omega-3 fatty acids found in fish oil, such as docosahexaenoic acid and eicosapentaenoic acid, could benefit individuals with AD have existed for some years. A recent Cochrane review found no evidence of significant adverse effects, but also no benefit on cognition, function, dementia severity, or quality of life in people with AD.[138] There is insufficient evidence now to recommend omega-3 fatty acids for the treatment of AD.

Medications and Treatment Strategies in Development

New medication development is focused on disease-modifying and prevention strategies and has fallen broadly into several categories: treatments designed to reduce levels of brain Aβ or manipulate its configuration, treatments targeting tau protein, anti-inflammatory approaches (eg, cytokines, microglial cells), and therapies targeting glutaminergic and cholinergic response (eg, sigma receptors, AMPA-kines). Interest in targeting early, prodromal AD has also risen. The NIA-AA Research Framework provides guidance for biomarker testing to capture such early disease which relies on assessment of three criteria: (1) presence of neurodegeneration, (2) presence of amyloid, or (3) presence of tau in the brain using specific imaging of CSF sampling techniques.[44,139,140]

Although many potential new medications have advanced to early clinical studies, no new agents had entered the market since 2004, until the approval of aducanumab. While progress has been made in developing novel biomarkers and improving RCT designs, results remain disappointing.[25,59,60,94,95] One reason for the failure of so many AD therapies may be that current strategies do not target the pathways that ultimately result in AD. Another reason may be that medications are being initiated when the disease has already progressed too far to be reversed.[25] Focus on the amyloid hypothesis of AD, and to a lesser extent on tau, may have led to discounting other treatment approaches. AD is likely a multifactorial condition, which suggests that a single approach will not prevent or treat AD in all patients. Some of the potential targets of interest going forward include dysfunction of neuronal networks, inflammation, infectious agents such as herpes virus or prions, accumulation of neurotoxic proteins related to sleep deprivation and blood–brain barrier dysfunction, mitochondrial dysfunction, environmental factors, and conditions affecting brain vascular health including diabetes, obesity, hypertension, and hypercholesterolemia.[25] There is also a great deal of attention to identify AD biomarkers and recommendations are likely to evolve over time as we better understand the underlying disease pathophysiology and predictors of patient response. Regardless, now there are no specific recommendations regarding the choice of medication, dosing regimen, or treatment duration for cognitive agents (ie, cholinesterase inhibitors and memantine) based on genotype or other biomarkers.

Given the exponentially increasing number of individuals and families facing the diagnosis of AD, government leaders of G7 countries have strategized to drive innovation and improve the quality of life for people affected by AD, by establishing a goal to find a cure or disease-modifying therapy by 2025.[141] This effort resulted in more research directed toward achieving this goal. Furthermore, the National Institutes of Health, FDA, pharmaceutical companies, and nonprofit organizations joined together to form the "Accelerating Medicines Partnership" to create networks, share data, and manage RCTs.[142]

Pharmacotherapy of Neuropsychiatric Symptoms

Most patients with AD manifest neuropsychiatric symptoms (also referred to as BPSD) at some point in the illness.[143-145] These symptoms can be roughly divided into four categories: (1) psychotic; (2) hyperactive (eg, inappropriate or disruptive behavior); (3) affective (eg, depression); and (4) apathy.[143,144] Effective management of BPSD is important because symptoms are distressing to both the patient and caregiver, necessitate increased caregiver supervision and patience. Escalating and cahlenging BPSD is a leading reason for nursing home placement.

⑩ Strategies for treatment of BPSD should include nonpharmacologic interventions first, followed by pharmacologic interventions when necessary. Behaviors, such as agitation, aggression, delusions, hallucinations, repetitive vocalizations, and wandering, may be caused by medications, medical illness (eg, pain, constipation, dehydration, infection), environmental precipitants, physical/verbal abuse, or unmet physical and psychological needs. Correcting possible underlying causes before initiating medication therapy is critical.[145,146] The need for medications may arise when neuropsychiatric symptoms are of sufficient severity to cause significant distress to the patient or caregiver, interfere with function or cause disability, impede delivery of necessary care, or pose a danger to self or others and have not responded to nonpharmacologic interventions.[53,112,145-147] The balance between potential risks and expected benefits of the intended medication must be acceptable to the patient or surrogate decision maker. Medications should be used cautiously, with adequate monitoring for effectiveness and adverse events.

Despite the high prevalence of neuropsychiatric symptoms in AD, relatively little research has been conducted, and no medication is approved by the FDA for the treatment of BPSD, however clinical trials are ongoing.[140] Considering limited clinical data, treatment is primarily empiric, with adverse effect profiles used as a guide in selecting the appropriate treatment. For instance, psychotropic medications with anticholinergic effects should be avoided because they may worsen cognition and interfere with cholinesterase inhibitor therapy.

General guidelines governing pharmacologic therapy for BPSD can be summarized as follows: reserve for situations where nonpharmacologic therapies failed, use reduced doses, monitor closely, titrate dosage slowly, minimize duration of therapy, attempt tapers, and document carefully. Treatment should be considered temporary.[146] Caregivers may have unrealistic expectations regarding the effects of these medications, and the anticipated benefits and risks should be clearly explained. Disruptive behaviors and delusions wax and wane with disease progression, and some behaviors (eg, wandering, hoarding, screaming, repetitive behaviors) lack evidence of a medication response.[148] Attempts to slowly taper and discontinue medication should be undertaken regularly in minimally symptomatic patients, as behaviors often fluctuate, changing in character and intensity over time, and the medication may no longer be providing a benefit.[145,146]

Cholinesterase Inhibitors and Memantine

Cholinesterase inhibitors and memantine may be beneficial in both managing BPSD and reducing their incidence.[144] While cholinesterase inhibitors may improve apathy, depression, tension, and irritability in mild-to-moderate dementia, they do not appear to significantly reduce acute agitation.[144] Memantine may show modest benefit for mitigating agitation, aggression, delusions, and hallucinations; however, recent trials of memantine specifically evaluating its effect on treating agitation in people with AD found no benefit.[144] These benefits should be considered along with cognitive benefits in treatment decisions and weighed against their adverse effects. Long-term effects on behavior have not been demonstrated and further research is needed.

Antidepressants

Antidepressants may be prescribed for BPSD to help manage depression, anxiety, apathy, as well as agitation and aggression. Depressive symptoms and anxiety are common in people with AD. Apathy is seen in 48% to 92% of individuals with dementia, and clinically significant depression occurs in approximately 32% with mild dementia, 23% with moderate disease, and 18% in the severe stage of the dementia.[149] Results of trials studying the efficacy of antidepressants in treating depression in people with AD are conflicting,[145] and improvement among participants receiving placebo is also common. In practice, treatment with selective serotonin reuptake inhibitors (SSRIs) is initiated most commonly in people with AD, based on adverse effect profile, risk of interactions, and evidence of efficacy.[145] Among the SSRIs, the best evidence exists for sertraline and citalopram.[72,145] Serotonergic function may also play a role in some of the other BPSD of AD, such as agitation, and some studies support the use of SSRIs in managing these behaviors, even in the absence of depression.[145] Clinical trials are needed to compare the efficacy of SSRIs to second-generation antipsychotics (SGAs). Tricyclic antidepressants should generally be avoided because of their anticholinergic activity.[144] Chapter 88 has a more complete discussion of treatment of depression.

Antipsychotics

Antipsychotics are used in the management of neuropsychiatric symptoms in AD despite efforts by the Centers for Medicare and Medicaid Services and other groups to reduce their use in nursing homes.[150] No antipsychotic has gained FDA approval for management of BPSD in AD. There is modestly convincing evidence that certain SGAs provide some benefit for particular neuropsychiatric symptoms with the most studied being aripiprazole, risperidone, olanzapine, and quetiapine. More than 20 RCTs have evaluated SGAs for BPSD, with more than 5,000 patients participating and treatment durations of 6 to 26 weeks for most trials.[151] A meta-analysis of 16 trials demonstrated the efficacy of aripiprazole, risperidone, olanzapine, and quetiapine over placebo; however, they were associated with a higher risk of adverse medication reactions. The investigators concluded the increased risk of adverse reactions and mortality may offset the benefit. An outpatient RCT of 421 people with AD and psychosis, aggression, or agitation randomized to receive olanzapine, quetiapine, risperidone, or placebo for up to 36 weeks found no significant differences among treatments in time to treatment discontinuation or improvement based on the Clinical Global Impression–Change (CGI-C) response. The investigators concluded that adverse medication reactions may offset the therapeutic advantages of SGAs for treatment of psychosis, aggression, or agitation in people with AD.[152]

Adverse medication reactions are common with first-generation antipsychotics (FGAs) and SGAs in people with AD and include somnolence, extrapyramidal symptoms, abnormal gait, cerebrovascular events, and increased risk of de[154]ath.151 Compared to SGAs, FGAs are associated with more severe extrapyramidal effects and hypotension. In 2005, the FDA mandated the addition of a boxed warning to all SGAs due to increased risk of mortality in older adults with dementia-related psychosis; this warning was expanded in 2008 to include all FGAs as well.[153] Mortality was mostly cardiovascular (eg, sudden death, heart failure) or infectious (eg, pneumonia) in nature. In 2011, the Office of Inspector General released a report which described that the majority (83%) of SGA prescription claims were for nursing home residents without FDA-approved indications.[154] In 2012, the Centers for Medicare and Medicaid Services launched the National Partnership to Improve Dementia Care in Nursing Homes to improve quality of care for nursing home residents with dementia. Although the percentage of residents receiving antipsychotic therapy has since decreased, from 23.9% in 2011 to 14.5% in 2020, about 1 in 6 people living in nursing homes are receiving antipsychotic medications.[150,155]

There is a modest expectation of treatment benefit and a potential for significant harm associated with antipsychotic use in people with AD. Individual risk and benefit must be considered and discussed with family and caregivers when initiating therapy. Prescribing of antipsychotics in AD should be restricted to patients with severe symptoms not responding to other measures, and treatment should be tapered as early as possible.[146,147] Doses should be initiated at one-third to one-half of the usual adult starting dose (or with smallest available tablet strength), and target doses are much lower than those for other indications.[146] The American Psychiatric Association (APA) guidelines recommend tapering and discontinuing the antipsychotic after 4 weeks at an adequate dose if no clinical benefit is seen. If benefit is seen, an attempt to taper should be made 4 months after initiation, to reduce risk of harm as original need for the medication may change.[146] A meta-analysis of RCTs of antipsychotic discontinuation showed no significant increase in BPSD severity upon discontinuation compared to the continuation group.[156] For patients continued on antipsychotics, monitor for tardive dyskinesia and metabolic effects. Chapter 87, “Schizophrenia” includes a more detailed discussion of antipsychotic monitoring.

Miscellaneous Therapies

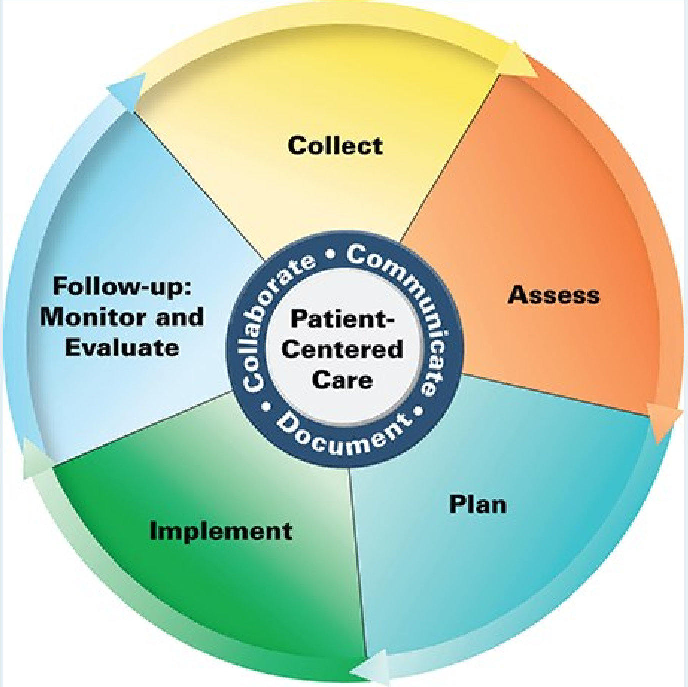
Because antipsychotic and antidepressant therapies have only modest efficacy and pose the potential for undesirable adverse effects, medications traditionally used to treat disruptive behaviors and aggression in other psychiatric and neurologic disorders have been suggested as potential alternatives. These alternatives include benzodiazepines and antiseizure medications.[145]

Benzodiazepines have been used to treat anxiety, agitation, and aggression, but the benefit is unclear especially given the risk of sedation, falls, impaired cognition, respiratory depression, and paradoxical disinhibition.[144] Evidence for their use in BPSD is lacking. Antiseizure medications used as “mood stabilizers” such as carbamazepine, lamotrigine, gabapentin, and pregabalin may have some benefit but evidence is limited or conflicting.[157] Adverse effects and interactions of carbamazepine often outweigh benefits. Valproic acid is no longer recommended as a result of an association of mood stabilizers with severe adverse reactions in patients with BPSD.[143,144] In general sedative hypnotics including benzodiazepines and benzodiazepine receptor agonists (eg, zolpidem) should be avoided as the risk of harm (eg sedation, falls) outweighs the benefit.[52] Melatonin and ramelteon have been used for circadian rhythm disturbances. More recently, suvorexant, an orexin antagonist, was studied for insomnia in patients with mild-to-moderate AD showing improvement in total sleep time and wake after sleep onset. Somnolence and falls occurred in the suvorexant treated groups.[158]

Neuropsychiatric symptoms are often the most difficult aspect of AD for the caregiver. When nonpharmacologic approaches fail, selected antipsychotics and antidepressants may be useful for effective management of behavioral, psychotic, and depressive symptoms, thereby easing caregiver burden and allowing the patient to spend additional time at home. All too often, however, nonpharmacologic measures are not implemented appropriately, and medication overuse is an ongoing problem. Adverse events remain an important concern in this population as well.

PATIENT CARE PROCESS

Patient Care Process for Alzheimer Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, race)
- Patient history (eg, past medical, family, social history)
- Collateral information from family, friends and caregivers
- Current medications including medications that may cause or worsen cognitive, neuropsychiatric, and/or functional symptoms (see list of common offending agents, in “Assess”)
- Assessments for cognitive, neuropsychiatric, and functional symptoms; for example:
    - Mini-Mental State Examination or Montreal Cognitive Assessment (cognition)
    - Neuropsychiatric Inventory (behavioral disturbances)
    - Bristol Activities of Daily Living Scale (function)
- Laboratory data
    - Comprehensive metabolic panel, including electrolytes, glucose, and liver function tests
    - Complete blood cell count
    - Serum B_{12}, homocysteine and/or methylmalonic acid testing
    - Thyroid function tests
    - Rapid plasma reagin and human immunodeficiency virus testing
    - Urinalysis and/or chest x-ray

- Other Diagnostic Tests
    - CT or MRI scans

Assess

- Risk factors for AD (eg, age, family history, low education level, smoking)
- Cognitive symptoms (eg, memory loss, aphasia, apraxia, agnosia, disorientation, impaired executive function)
- Neuropsychiatric symptoms (eg, depression, psychotic symptoms, behavioral disturbances)
- Functional symptoms (eg, inability to care for self), including patient's ability to manage and self-administer their own medications
- Medications that may cause or worsen cognitive, neuropsychiatric, and/or functional symptoms; for example:
    - Benzodiazepines and other sedative hypnotics
    - Anticholinergics
    - Opioid analgesics
    - Antipsychotics
    - Antiseizure medications
    - Skeletal muscle relaxants
- Labs, diseases or syndromes that may cause or worsen cognitive, neuropsychiatric, and/or functional symptoms; for example:
    - Alcohol or substance use
    - Depression
    - B_{12} or folate deficiency
    - Hyperhomocysteinemia
    - Hypothyroidism and hyperthyroidism
    - Electrolyte disturbances (eg, hyponatremia)
    - Glucose abnormalities (eg, hypoglycemia)
    - Infectious processes (eg, tertiary syphilis, human immunodeficiency virus, urinary tract infection)
    - Complete blood count to rule out anemia or infection
    - Vision, hearing, or other sensory impairments
    - Other common types of dementia in late life (see Table 73-1)
- Stages of AD (see Table 73-2 and Fig. 73-1)
- Appropriateness of current living situation (eg, independent living, assisted living, nursing home)
- Appropriateness and effectiveness of current medication regimen

Plan*

- Tailored lifestyle modifications (eg, diet, physical activity) for management of brain vascular health
- Medication therapy regimen for cognitive symptoms (if appropriate) including specific medication(s), dose, route, frequency, and intended duration; specify the continuation and discontinuation of existing therapies (see Table 73-3 and Table 73-6)
- Monitoring parameters including efficacy, safety (medication-specific potential adverse medication reactions), and time frame (see Table 73-7)
- Patient, family, and caregiver education (eg, risks vs benefits of treatment, expected outcomes, medication therapy selection)
- Referrals to other health professionals when appropriate (eg, social work, psychology, occupational therapy)

Implement*

- Provide patient, family, and caregiver education regarding all elements of treatment plan
- Provide caregiver access to local and national resources (see Table 73-5)
- Provide family and caregiver education regarding basic principles of care for the patient with AD (see Table 73-4)
- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Presence of adverse effects related to medications for cognitive symptoms
- Disease progression, including incidence or worsening of neuropsychiatric symptoms of dementia in accordance with standard assessment tools (see list of commonly used assessments, in "Collect")
- Patient adherence to treatment plan using multiple sources of information
- Patient, family, and caregiver expectations

**Collaborate with patients, caregivers, and other healthcare professionals.*

EVALUATION OF THERAPEUTIC OUTCOMES

An evaluation of therapeutic outcomes in the person with AD begins with a thorough assessment at baseline and a clear definition of therapeutic goals. Cognitive status, functional performance, mood, and behavior all need to be evaluated before initiation of medication therapy. The clinician should interview both the patient and the caregiver to assess response to medication therapy. In evaluating response to cognitive agents, the clinician should ask questions about the patient's ability to perform daily functional tasks, mood and behavior, and memory and orientation. Objective assessments (eg, MMSE for cognition, Bristol Activities of Daily Living Scale for function, Neuropsychiatric Inventory for behavioral disturbances) can be used to quantify changes over time.[159]

Because target neuropsychiatric symptoms of dementia may manifest differently, a detailed list of target symptoms should be documented in the pharmacotherapy plan to aid in monitoring. These could include, for example, "striking at spouse because patient believes they are an impostor" or "verbal threats and refusal to allow clothes to be changed," as opposed to documenting vague symptoms, such as "aggression" or "delusions." To make an accurate assessment of depression, multiple symptoms (eg, sleep, appetite, activity, interest levels) need to be considered in addition to the patient's stated mood. As noted above, the failure of pharmacologic modalities to impact these target symptoms should result in discontinuation. If responses are seen, tapering and subsequent monitoring for recurrence should be undertaken.

The patient should be observed carefully for potential adverse effects of medication therapy, including the specific adverse effect and how it is being assessed. Consensus on the frequency of monitoring is lacking, but patients should generally be monitored for adverse events within 2 to 4 weeks of initiation of therapy, for therapeutic effect in 8 to 12 weeks, and at least every 3 to 6 months thereafter.[160] The effects of cognitive agents will not necessarily be obvious, and a treatment period of several months to a year may be necessary before it can be determined whether therapy is beneficial. Cognitive effects of the medication are often noticed only as a plateauing during treatment or as deterioration following medication discontinuation. In general, cognitive agents should be continued if the patient is demonstrating no change in clinical status. If there is doubt, the medication can be slowly tapered and discontinued, and the patient monitored off the medication for 4 to 6 weeks to determine the need for continued therapy. Medication deprescribing for people with AD is aided by the availability of deprescribing guidelines and algorithms for antipsychotics, cholinesterase inhibitors, and memantine.[161] The question of when, if ever, to stop medication therapy for AD remains controversial. Treatment benefits are not always evident, and fear of deterioration can lead to patients being prescribed medication therapy for AD from the time of their diagnosis until death. Some clinicians recommend withdrawing medication therapy if the patient significantly deteriorates in cognition or function, while others wait until the patient has lost all cognitive and functional abilities. Tolerability, cost, and patient and family preferences factor heavily into medication therapy discontinuation decisions. If cholinesterase inhibitors are discontinued and cognition worsens or behavioral issues emerge, the medications can be reinitiated.

CONCLUSION

Ultimately, AD, as with other dementias, is a complex condition to evaluate and manage. Clinicians are encouraged to work interprofessionally and collaborate closely with patients and their families to minimize stigma, identify therapeutic goals, and address concerns as they arise.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is the most common form of dementia among older adults?

   A. Lewy body dementia

   B. Vascular dementia

   C. Alzheimer disease

   D. Organic brain syndrome

2. Genetic susceptibility to late-onset AD is primarily linked to which of the following?

   A. Apolipoprotein E4 genotype

   B. Presenilin gene mutations

   C. Amyloid precursor protein mutations

   D. Apolipoprotein E2 genotype

3. Which of the following statements is TRUE regarding the pathophysiology of AD?

   A. AD is caused by amyloid plaques.

   B. AD is caused by neurofibrillary tangles.

   C. AD is caused by inflammatory brain processes.

   D. The cause of AD is not completely understood.

4. When initiating pharmacologic treatment for a patient with a new diagnosis of AD, which of the following would be the safest and most effective option?

   A. Vitamin E

B. Donepezil

C. *Ginkgo biloba*

D. Memantine

5. Which cholinesterase inhibitor inhibits both butyrylcholinesterase and acetylcholinesterase?

A. Donepezil

B. Galantamine

C. Memantine

D. Rivastigmine

6. What is the route of administration of aducanumab?

A. Oral

B. Intravenous

C. Transdermal

D. Intramuscular

7. Which of the following interventions is considered first-line therapy for behavioral and psychological symptoms of dementia?

A. Sertraline

B. Quetiapine

C. Carbamazepine

D. Multisensory stimulation

Please use the following case for Questions 8-10:

An 87-year-old patient was diagnosed with AD and vascular dementia 2 years ago. At that time, donepezil 5 mg daily was started and continued at that dose. The patient denies any difficulty tolerating the medication and also takes warfarin and metoprolol for atrial fibrillation and lisinopril for hypertension. The patient's spouse notes that the patient's memory has declined significantly over the last several months.

8. Which of the following statements is TRUE regarding this patient's donepezil therapy?

A. Patient is receiving an appropriate maintenance dose of donepezil.

B. Patient has not been titrated to the target maintenance dose of donepezil.

C. Donepezil is not an appropriate therapy for a patient in this stage of AD.

D. Donepezil should be avoided in this patient due to vascular dementia and atrial fibrillation.

9. The patient's spouse confides in you that they plan to the start patient on a supplement for brain health that contains *Ginkgo biloba*. What would be the most appropriate advice to offer to the patient's spouse regarding *Ginkgo biloba*?

A. *Ginkgo biloba* is an appropriate therapy because it is more effective than donepezil.

B. *Ginkgo biloba* should be avoided because of its potential to worsen cognitive outcomes.

C. *Ginkgo biloba* should be avoided because of its potential drug interaction with warfarin.

D. *Ginkgo biloba* is appropriate because it is effective for treating both AD and atrial fibrillation.

10. Which of the following is an appropriate recommendation for the patient's spouse regarding management of this patient's cardiovascular disease?

A. Hypertension control is no longer necessary.

B. The risks of continuing warfarin outweigh the potential benefits.

C. Clopidogrel and aspirin should be added to patient's drug regimen to improve vascular health.

D. Treating hypertension and atrial fibrillation is recommended to optimize brain vascular health.

Please use the following case for Questions 11 and 12:

An 84-year-old patient was diagnosed with AD 4 years ago. Symptoms first became apparent to family about 1 year before the diagnosis was made. Current Mini-Mental State Examination (MMSE) score is 14. The patient is unable to perform most activities of daily living and does not recognize caregivers on some days.

11. Which of the following medications/medication combinations has NOT been shown to be effective therapy for this patient's stage of AD?

A. Aducanumab 10mg/kg every 4 weeks

B. Donepezil 10 mg nightly at bedtime

C. Memantine 10 mg twice daily

D. Donepezil 10 mg nightly at bedtime + memantine 5 mg twice daily

12. The patient's spouse asks about using Tylenol PM to help the patient fall asleep. What would you recommend?

A. Tylenol PM is preferred over prescription sedative hypnotics to treat insomnia in patients with AD.

B. Tylenol PM is preferred for both pain and insomnia because it may enhance the effects of cholinesterase inhibitors in patients with AD.

C. Tylenol PM should be avoided because of the pharmacokinetic drug interaction between diphenhydramine and memantine.

D. Tylenol PM should be avoided because diphenhydramine may worsen cognitive function.

13. A 77-year-old patient was diagnosed with AD 2 months ago with an MMSE score of 22 at diagnosis. At that time, donepezil was started at 5 mg nightly at bedtime. Would it be considered appropriate to add memantine to the medication regimen now?

A. Yes, patient has moderate AD.

B. Yes, patient is unlikely to respond to donepezil.

C. No, patient has mild AD.

D. No, memantine should never be added to cholinesterase inhibitor therapy.

14. Of the following, which is the most common adverse medication reaction of donepezil?

A. Elevated blood pressure

B. Tachycardia

C. Agitation

D. Diarrhea

15. Which of the following counseling points would be appropriate to discuss with a newly diagnosed patient and their family in regard to expectations of AD therapy?

    A. Combination therapy with a cholinesterase inhibitor plus memantine usually halts the progression of AD.

    B. Risks of adverse mediation reactions outweigh the benefits in mild AD.

    C. Time to reach significant functional decline may be delayed by medication therapy but AD will continue to progress.

    D. Memory noticeably improves for most patients with AD when therapy is first initiated.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The majority (60%-80%) of dementia cases are AD. See "Epidemiology" section for more information.

2. **A.** Apolipoprotein E (*APOE*)*4 is the main genetic risk factor associated with for late-onset AD. See "Etiology" section (Etiology and Genetics) for more information.

3. **D.** A multitude of genetic, environmental, and possibly additional unknown variables contribute to development of AD. See the "Etiology" and "Pathophysiology" sections for more information.

4. **B.** Of the options listed, donepezil has the most safety and efficacy data to support its use. See "Treatment" section for more information about cholinesterase inhibitors, memantine, and dietary supplements.

5. **D.** Rivastigmine inhibits both butyrylcholinesterase and acetylcholinesterase. See "Treatment" section (Cholinesterase Inhibitors) for more information.

6. **D.** The route of administration of aducanumab is intravenous. This information can be found in Table 73-3.

7. **D.** Nonpharmacologic interventions are first line for neuropsychiatric symptoms of dementia. See "Treatment" section (Pharmacotherapy of Neuropsychiatric Symptoms) for more information.

8. **B.** The patient has been treated with donepezil 5 mg daily for 2 years. As they are not experiencing any bothersome adverse medication effects and have no known contraindications to increasing the dose, it would be appropriate to trial donepezil 10 mg daily. Since they are on metoprolol, monitoring for bradycardia should be included in your monitoring plan. Dosing information and monitoring parameters can be found in Tables 73-3 and 73-7.

9. **C.** The risks of using *Ginkgo biloba* outweighs the benefits in this patient. While heavily studied, convincing data to support the utility of Ginkgo biloba in AD is lacking. Moreover, in this case, *Ginkgo biloba* may potentiate the bleeding risk associated with warfarin. See "Treatment" section (*Ginkgo biloba*) for more information.

10. **D.** Vascular health plays a significant role in vascular dementia and AD. As such, the patient's diagnosis of dementia does not negate their need for ongoing management of cardiovascular disease. See "Pathophysiology" section (Brain Vascular Disease and High Cholesterol) and "Treatment" section (Management of Brain Vascular Health) for more information.

11. **A.** There is no data to support effectiveness of using aducanumab in moderate AD. See "Treatment" section for more information.

12. **D.** Tylenol PM contains both acetaminophen and diphenhydramine, the latter of which is strongly anticholinergic. Anticholinergic medications are known to contribute to cognitive impairment and, as such, should be avoided in this patient. See "Clinical Presentation" section (Diagnosis) for more information.

13. **C.** As the patient is newly diagnosed with mild AD and is still taking the lowest possible dose of donepezil, adding memantine does not seem necessary now. It would be reasonable, however, to consider increasing the donepezil dose to 10 mg daily if the patient is tolerating the drug well. As the patient's AD progresses, it may become necessary to increase the donepezil dose and/or add memantine. Dosing information can be found in Table 73-3.

14. **D.** Of the adverse medication reactions listed, diarrhea is most likely to be associated with donepezil. As cholinesterase inhibitors are procholinergic, patients may experience diarrhea and urinary incontinence. Cholinesterase inhibitors are associated with bradycardia, not tachycardia. Adverse drug event information can be found in Table 73-7.

15. **C.** It is important to be realistically optimistic with patients and their care partners, especially in the early stages of dementia. At present, there is no treatment option available to halt the progression of AD; however, some patients respond well to drug therapy, and large studies have shown the potential for medication use to delay functional decline and institutionalization. See "Treatment" section (Pharmacotherapy for Cognitive Symptoms) for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 74: Multiple Sclerosis

Jacquelyn L. Bainbridge; Augusto Miravalle; Pei Shieen Wong; Matthew J. Makelky; Sarah Rajkovic

KEY CONCEPTS

KEY CONCEPTS

① Multiple sclerosis (MS) etiology is unknown, but it appears to be autoimmune in nature. Currently, there is no cure.

② Multiple sclerosis is characterized by central nervous system (CNS) demyelination and axonal damage.

③ Multiple sclerosis is classified into several categories, differentiated by disease progression over time, clinical presentation, and response to therapy.

④ Studies only support one Food and Drug Administration (FDA)-approved disease-modifying therapy (DMT), ocrelizumab (Ocrevus), in patients with progressive forms of the illness. However, information derived from multiple studies suggests younger patients with progressive disease and those with either superimposed acute relapses or enhancing lesions on magnetic resonance imaging (MRI) scans may benefit from some of the presently used DMTs.

⑤ MS diagnosis is made primarily based on clinical symptoms and examination but does require evidence of dissemination of lesions over time in multiple parts of the CNS and/or optic nerve. Additional diagnostic criteria include use of MRI, spinal fluid evaluation, and evoked potentials to aid in the diagnosis.

⑥ Exacerbations or relapses of MS can be disabling and are treated with high-dose glucocorticoids, such as intravenous (IV) methylprednisolone. The onset of clinical response is typically within three to five days.

⑦ Treatment of relapsing-remitting multiple sclerosis (RRMS) with the DMTs interferon-β (IFN-β) (Avonex, Betaseron, Rebif, Extavia), glatiramer acetate (Copaxone), natalizumab (Tysabri), ocrelizumab (Ocrevus), mitoxantrone (Novantrone), fingolimod (Gilenya), siponimod (Mayzent), ozanimod (Zeposia), ponesimod (Ponvory), teriflunomide (Aubagio), dimethyl fumarate (Tecfidera), diroximel fumarate (Vumerity), monomethyl fumarate (Bafiertam), cladribine (Mavenclad), Ofatumumab (Kesimpta), and alemtuzumab (Lemtrada) can reduce the annual relapse rate, lessen relapse severity, slow progression of MRI changes, and slow progression of disability and cognitive decline. In addition, DMTs have been shown to reduce the likelihood of developing a second attack after a first clinically isolated syndrome (CIS) consistent with MS.

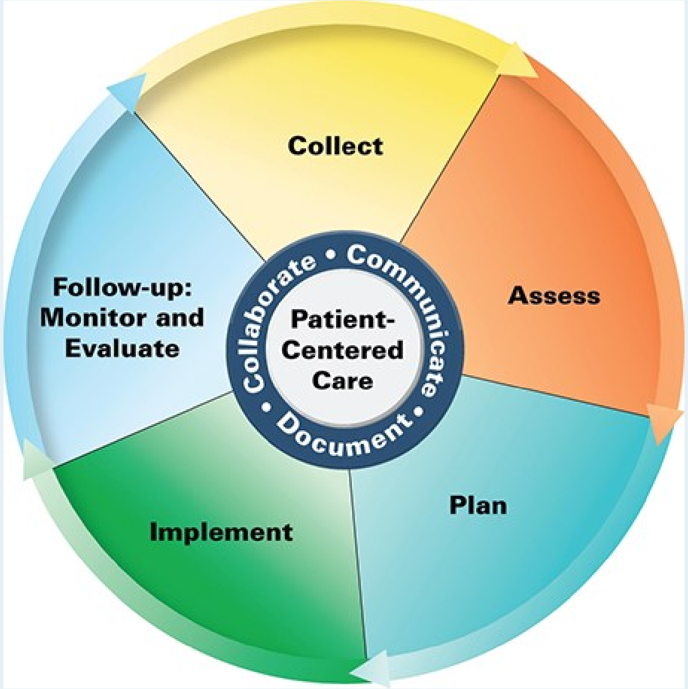
⑧ In most cases, treatment with DMTs should begin promptly after the diagnosis of RRMS or after a CIS if the brain MRI suggests a high risk of further attacks. Natalizumab, and other choices associated with problematic adverse events, should be reserved for those patients who have failed one or more standard therapies and those with poor prognostic signs.

⑨ The definition of "treatment inadequacy" for RRMS remains unclear, and therapy changes after "treatment failure" should be individualized.

⑩ Patients suffering with MS frequently have spasticity, bladder dysfunction, fatigue, neuropathic pain, cognitive dysfunction, and depressive symptoms that may require treatment. Providers must counsel patients that DMTs will not relieve these symptoms and that depression is common and can pose the risk of suicide.

PATIENT CARE PROCESS

Patient Care Process for Multiple Sclerosis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient-specific demographics such as age, race, gender, geographical places of residence before or after the age of 15, current smoking level and history, family history of MS, and previous infection with certain viruses
- Laboratory values such as vitamin D, liver function tests, complete metabolic panel, and complete blood count (CBC)
- Magnetic resonance imaging (MRI) of the brain and spinal cord with and without contrast
- Lumbar puncture for oligoclonal bands
- Visual-evoked potential results
- Optical coherence tomography (OCT)
- Current diagnosis and date of initial diagnosis and current and past medications

Assess

- Clinical classification of MS (RRMS, SPMS, or PPMS)
- Disease progression using the Expanded Disability Status Scale (EDSS), and MRI results
- Total number of disease exacerbations or relapses
- Duration of therapy and dose for current and past medications, adverse medication reactions experienced during treatment, and medication adherence

Plan*

- Choose a therapy that has the best risk versus benefit profile for use in the specific form of MS diagnosed, as well as patient-specific characterizations and previous treatment history (Tables 74-1 to 74-3)
- Choose a therapy with the best adherence profile (twice yearly infusion vs. three times weekly injectable), and more tolerable adverse medication reactions based on stratified risk factors (JC virus)
- Create a patient-specific monitoring plan based on the therapy chosen (Table 74-2)
- Identify the presence of secondary symptoms requiring pharmacologic management (Table 74-4)

Implement*

- Start primary MS therapy as soon as possible to decrease the chance for disease progression during treatment changes
- Figure 74-3 represents a potential algorithm for MS treatment
- Add pharmacologic treatment for secondary symptoms when appropriate
- Discuss with patients the role of complementary and alternative therapies (Table 74-5)

Follow-up: Monitor and Evaluate

- Safety of current DMT at each visit to ensure the current treatment is best for the specific patient
- Monitor for common adverse medication reactions with each specific DMT (Table 74-2) or any adverse medication reactions that are new once therapy is initiated or changed
- Treatment response (reduction in primary, secondary, and tertiary symptoms of MS) or the occurrence of exacerbations and relapses
- Yearly change in brain lesions via MRI
- Change in daily functioning using the EDSS and other clinical factors used to predict MS prognosis (Table 74-6)

Collaborate with patients, caregivers, and other healthcare professionals.

TABLE 74-1

Disease-Modifying Therapy

Medication	Brand Name	Indication	Initial Dose	Usual Dose	Comment
First-generation agents					
Self-injectables					
Interferon-β_{1a}	Avonex	Relapsing forms of MS	30 mcg (6 million IU) IM once weekly	30 mcg IM once weekly	Considered low potency interferon
	Rebif	Relapsing forms of MS	22 mcg SQ three times a week	22 or 44 mcg SQ three times a week	Considered a high potency interferon

Interferon-β_{1b}	Betaseron, Extavia	Relapsing forms of MS	250 mcg (8 million IU) SQ every other day	250 mcg SQ every other day	Betaseron/Extavia is considered a high potency interferon Pregnancy category C
Pegylated Interferon-β_{1a}	Plegridy	RRMS	6.3 mcg SQ day 1, then 94 mcg SQ on day 15, then 125 mcg SQ on day 29, then 125 mcg SQ every 14 days	125 mg SQ every 14 days	Can pre-medicate or concurrently use an antipyretic/analgesic for flu-like symptoms Pregnancy category C
Glatiramer acetate	Copaxone, Glatopa	CIS, RRMS	20 mg SQ once daily or 40 mg SQ three times a week	20 mg SQ once daily or 40 mg SQ three times a week	Glatopa is the generic version of Copaxone Pregnancy category B
IV infusion					
Mitoxantrone	Novantrone	SPMS and worsening RRMS	12 mg/m^2 IV every 3 months	12 mg/m^2 IV every 3 months	Lifetime dose should not exceed 140 mg/m^2 Pregnancy category D
Second-generation agents					
Oral					
Fingolimod	Gilenya	Relapsing forms of MS, in patients 10 years and older	Adult: 0.5 mg orally once daily. Pediatric: <40 kg 0.25 mg orally once daily, >40 kg 0.5 mg orally once daily	Adult: 0.5 mg orally once daily. Pediatric: <40 kg 0.25 mg orally once daily, >40 kg 0.5 mg orally once daily	Medication Guide Required Pregnancy category C
Siponimod	Mayzent	Relapsing forms of MS	CYP2C9 *1/*1, *1/*2, *2/*2: 0.25 mg once daily on days 1 and 2, then 0.5 mg once daily on day 3, then 0.75 mg once daily on day 4, then 1.25 mg once daily on day 5. CYP2C9 *1/*3, *2/*3: 0.25 mg once daily on days 1 and 2, then 0.5 mg once daily on day 3, then 0.75 mg once daily on day 4	CYP2C9 *1/*1, *1/*2, *2/*2: 2 mg once daily beginning on day 6. CYP2C9 *1/*3, *2/*3: 1 mg once daily beginning on day 5	Medication Guide required. May cause fetal harm. CYP2C9 genotype testing required prior to initiating dose
Ozanimod	Zeposia	Relapsing forms of MS	0.23 mg once daily on days 1-4, then 0.46 mg once daily on days 5-7	0.92 mg once daily beginning on day 8	Medication Guide required. May cause fetal harm.
Ponesimod	Ponvory	Relapsing forms of MS	2 mg on days 1 and 2, 3 mg on days 3 and 4, 4 mg on days 5 and 6, 5 mg on day 7, 6 mg on day 8, 7 mg on day 9, 8 mg on day 10, 9 mg on day 11, 10 mg on days 12 - 14	20 mg on day 15 and thereafter	Medication Guide required. May cause fetal harm.

Dimethyl fumarate	Tecfidera	Relapsing forms of MS	120 mg delayed release twice daily for 7 days	240 mg delayed release twice daily	Pregnancy category C
Diroximel fumarate	Vumerity	Relapsing forms of MS	231 mg twice daily for 7 days	462 mg twice daily	May cause fetal harm based on animal data
Monomethyl fumarate	Bafiertam	Relapsing forms of MS	95 mg twice daily for 7 days	190 mg twice daily	May cause fetal harm based on animal data
Teriflunomide	Aubagio	Relapsing forms of MS	7 mg orally once daily	7 or 14 mg orally once daily	Cholestyramine and charcoal accelerate teriflunomide elimination Pregnancy category X
Cladribine	Mavenclad	RRMS and active SPMS	3.5 mg/kg over 2-year treatment course, administered as 1.75 mg/kg in each year. Divide the 1.75 mg/kg dose over 2 cycles, each cycle lasting 4 to 5 consecutive days; do not administer more than 20 mg/day. In the first-year treatment course, initiate the first cycle at any time; administer the second cycle 23 to 27 days after the last dose of the first cycle	Second-year treatment course: Initiate the first cycle ≥43 weeks after the last dose of the first year's second cycle. Administer the second cycle 23 to 27 days after the last dose of the second year's first cycle. Following 2 years of treatment, do not administer oral cladribine during the next 2 years	Medication Guide required Contraindicated for use in females and males of reproductive potential. Lymphocytes must be within normal limits before initiating first treatment course and >800 cells/mm^3 (0.8 x10^9/L) before the second treatment course.
IV infusion					
Natalizumab	Tysabri	Relapsing forms of MS	300 mg IV every 4 weeks	300 mg IV every 4 weeks	REMS Program required Pregnancy category C
Alemtuzumab	Lemtrada	RRMS	First treatment course: 12 mg/day IV for 5 consecutive days (60 mg total dose)	Second treatment course: 12 mg/day IV for 3 consecutive days (36 mg total dose) administered 12 months after first treatment course	REMS Program required. Pregnancy category C. May pre-medicate with 1,000 mg methylprednisolone (or equivalent) immediately prior to infusion for first 3 days. Also, administer herpes viral prophylaxis starting on first day of treatment and continued for at least 2 months after completion of treatment or until CD4+ count is at least 200 cells/mm^3 (0.2 × 10^9/L), whichever occurs last
Ocrelizumab	Ocrevus	Relapsing forms of MS and	First treatment course: 300 mg IV followed by 300 mg IV 2 weeks later. Start infusion at 30 mL/hr,	Maintenance treatment (given 6 months after the end of first treatment, and	REMS Program required. Fetal risk cannot be ruled out. Premedication: antihistamine 30 to 60 minutes prior

		PPMS	then increase by 30 mL/hr every 30 minutes as tolerated to a maximum of 180 mL/hr for a duration of 2.5 hours or longer	every 6 months thereafter): 600 mg IV starting at 40 mL/hr and increased by 40 mL/hr every 30 minutes as tolerated to a maximum rate of 200 mL/hr for a duration of 3.5 hours or longer	to infusion and 100 mg methylprednisolone or equivalent corticosteroid 30 minutes prior to infusion. Can also consider and antipyretic. Observe patient for at least 1 hour post infusion.
Self-injectable					
Ofatumumab	Kesimpta	Relapsing forms of MS	20 mg once weekly for 3 doses (weeks 0, 1, 2)	20 mg once monthly starting at week 4	Medication Guide required. Single-dose prefilled syrine pen. Based on animal data, may cause fetal harm.

TABLE 74-2

Adverse Medication Reactions and Monitoring Parameters

Medication	Adverse Medication Reaction	Monitoring Parameter	Comments
Interferon-β_{1a}	Depression, flu-like symptoms, leukopenia, injection site reactions	Electrolytes, CBC, LFTs, thyroid function, LVEF, depression LFTs at baseline, 1 month, and every 3 months for a year, and every 6 months thereafter	Avoid use in untreated severe depression
Interferon-β_{1b}	Depression, injection site reactions, leukopenia, flu-like symptoms	Electrolytes, CBC, LFTs, thyroid function, depression	Avoid use in untreated severe depression More frequent injection site reactions reported
Glatiramer acetate	Injection site reactions, infection, hypersensitivity, chest tightness, urticaria	MRI, tissue necrosis, postinjection reaction	Chest tightness, urticaria can occur at any dose
Mitoxantrone	Bone marrow suppression, neutropenia, cardiotoxicity, AML, nausea, vomiting, diarrhea, alopecia	CBC, ECG, LVEF, LFTs	Secondary leukemia Lifetime maximum dose due to cardiac toxicity
Fingolimod	Lymphocytopenia, macular retinal edema, AV block, infection, headache	CBC, ECG, varicella zoster antibody, blood pressure, ophthalmic examination, LFTs	Requires first dose observation. Contraindicated in patients receiving Class I and III antiarrhythmic medications and those with recent cardiac diseases*, second- and third-degree AV block. Ketoconazole increases serum concentrations (3A4 inhibition). Vaccine efficacy may be decreased.
Siponimod	Infections, macular edema, bradyarrhythmia and atrioventricular conduction delays, decreased pulmonary function, liver injury,	CBC, ECG, varicella zoster antibody, blood pressure, ophthalmic examination, LFTs	Requires CYP2C9 genomic testing. Contraindicated in *3/*3 genotype. Medication interactions with 2C9 and 3A4 inhibitors and inducers.

	increased blood pressure		
Ozanimod	Infections (URTI), AV block, bradycardia, hepatotoxicity, increased blood pressure, lymphopenia, macular edema, neurotoxicity, PML, decreased pulmonary function, varicella zoster infections	CBC, ECG, varicella zoster antibody, blood pressure, ophthalmic examination, LFTs	Medication interactions with strong CYP2C8 inhibitors and inducers and BCRP inhibitors. Avoid use of live attenuated vaccines during and for up to 3 months after treatment.
Ponesimod	Infections, bradyarrhythmia and atrioventricular conduction delays, pulmonary function, liver injury, increased blood pressure, cutaneous malignancies, macular edema	CBC, ECG, LFTs, ophthalmic examination, varicella zoster antibody	Contraindicated in patients with recent cardiac diseases*, second- and third-degree AV block, sick sinus syndrome, or sino-atrial block unless patient has functioning pacemaker. Four-hour observation monitoring for patients with certain preexisting cardiac conditions.
Dimethyl fumarate	Flushing, rash, pruritus, GI discomfort, lymphocytopenia, increased LFTs, albuminuria, PML	CBC, LFTs, MRI	Taking with food decreases incidence of flushing
Diroximel fumarate	Flushing, GI upset, hepatotoxicity, infections, lymphopenia, PML	CBC, LFTs, MRI	Less GI adverse events compared to dimethyl fumarate and may be better tolerated
Monomethyl fumarate	Flushing, GI upset, hepatotoxicity, infections, lymphopenia, PML	CBC, LFTs, MRI	Less GI adverse events compared to dimethyl fumarate and may be better tolerated
Teriflunomide	Steven-Johnson syndrome, liver failure, neutropenia, respiratory infection, activation of TB, alopecia, neuropathy	CBD, LFTs, blood pressure, pregnancy, TB test	Contraindicated in severe hepatic impairment. Possibility of TB reactivation. Active metabolite of leflunomide
Cladribine	Bone marrow suppression, cardiotoxicity, hepatotoxicity, infection, malignancy, neurotoxicity, PML, renal toxicity, hypersensitivity, headache	CBC before starting, 2 and 6 months after the first course of each cycle and periodically. HIV, HBV, HCV, TB screening, VZV antibody, pregnancy test, LFTs, MRI, PML, infection	Contraindicated with current malignancy, HIV infection or active chronic infections, pregnancy and lactation
Natalizumab	PML, depression, fatigue, respiratory infection, arthralgia, hepatotoxicity	JCV antibody, infection, MRI, LFTs, hypersensitivity reactions,	Risk of PML. Risk of IRIS when discontinued due to PML
Alemtuzumab	Infusion reactions, infections (nasophyaryngitis, UTI, URI, herpes viral infections), autoimmune disorders, thyroid disorders, immune-mediated thrombocytopenic purpura, goodpasture syndrome	CBC, thyroid function, antibodies to varicella zoster virus, HPV screening, serum creatinine, TB prior to treatment, infusion reactions, skin exams, urinalysis	Contraindicated with HIV infection. Birth control should be used during treatment and for 4 months after each treatment course. Nursing is not recommended during treatment and for 4 months following each treatment course.
Ocrelizumab	Infusion reactions, nasopharyngitis, upper respiratory tract infection, headache, urinary tract infection,	MRI, active infection before infusion, infusion reactions during and after infusion, skin	Live vaccines are not recommended during treatment and after treatment until B-cell repletion, administer all live vaccines 6 weeks before treatment Evaluate for

	herpes virus-related infections, neoplasms	infections	Hepatitis B infection before first dose Avoid pregnancy during treatment and for 6 months after stopping treatment
Ofatumumab	Infections, injection site reactions, reduction in immunoglobulins, headache	HBV screen, serum immunoglobulins, CBC, PML, MRI	Contraindicated in active HBV infection. Immunize at least 4 weeks prior to initiation for live or live-attenuated vaccines and 2 weeks prior for inactivated vaccines

*Cardiac disease including myocardial infarction, unstable angina, stroke, transient ischemic attack, and heart failure NYHA Class III/IV.

AML, acute myeloid leukemia; CBC, complete blood count; ECG, electrocardiogram; LVEF, left ventricular ejection fraction; IRIS, immune reconstitution inflammatory syndrome; PML, progressive multifocal leukoencephalopathy; LFT, liver function test.

TABLE 74-3

Key Recommendations on Treatment and Access Considerations

- Initiating therapy with an FDA-approved DMT is recommended as soon as possible following a definite diagnosis of relapsing MS. It can also be considered for selected patients with a first clinical attack consistent with MS where other potential causes have been excluded, as well as for patients with progressive MS with clinical relapses and/or inflammatory activity
- Choice of initial or alternative DMT is complex and should be collaboratively done by the treating clinician and the patient.
- Clinicians should evaluate barriers to treatment adherence and counsel patients on its importance
- Continue therapy indefinitely unless there is a clear lack of benefit, intolerable adverse medication reactions, inadequate patient adherence, new data that reveal other reasons for cessation, or a better therapy becomes available.
- The absence of relapses while on treatment should not justify treatment discontinuation. When switching DMTs due to suboptimal response, choose an agent with an alternative mechanism of action.
- For patients with highly active MS, clinicians should prescribe alemtuzumab, fingolimod, or natalizumab.
- Natalizumab can be initiated in patients with MS and positive anti-JCV antibody indexes above 0.9 only when there is a reasonable benefit outweighing the severe but low risk of PML.
- Ocrelizumab can be offered to patients with PPMS when the risks of treatment does not outweigh the benefits.
- Clinicians should counsel female patients to stop their DMT before conception for planned pregnancies. If accidental exposure occurs, clinicians should discontinue DMTs during pregnancy. They should not be initiated during pregnancy unless the risk of MS activity outweighs the DMT risk.
- Due to the significant variability in therapeutic response, contraindications, risk tolerance, and treatment adherence seen in the MS population, patient and clinician access to all available therapies is necessary as this may influence decisions regarding the route of administration and/or adverse medication effect tolerance.
- Patient access to medication should not be limited by the frequency of relapses, age or other personal characteristics, or level of disability. Therapy should not be withheld to allow for determination of coverage by payers, as this puts the patient at increased risk for recurrent disease activity.

BEYOND THE BOOK

BEYOND THE BOOK

Create a table that lists the current FDA-approved multiple sclerosis (MS) therapies for relapsing-remitting MS (RRMS), primary progressive MS (PPMS), clinically isolated syndrome (CIS), and secondary progressive MS (SPMS). Include the mechanism of action (MOA) and how you believe this helps reduce MS symptoms. This activity will get you familiar with MS medications and how they are used in practice for differing forms of the disease.

When treating MS there are many different approaches to the intensity of treatment. What are the risks and benefits of starting a patient on self-injected interferon therapy versus infused immunotherapy? Compare and contrast the decrease in MS symptoms and relapses with these therapies in respect to the adverse medication reactions seen with the same therapies. What adverse medication reactions are more common as years on treatment accumulate?

INTRODUCTION

Multiple sclerosis (MS) is a central nervous system (CNS) inflammatory disease that affects approximately 1 in 450 per 100,000 females and fewer males in the United States.[1] The term “multiple sclerosis” refers to two characteristics of the disease: multiple neurologic symptoms that accrue over time and characteristic plaques or sclerosed areas seen in numerous areas of the brain and spinal cord.

① MS was first described more than 140 years ago, but the cause remains a mystery, and a cure is still unavailable. However, many recent advances in disease treatment and complication management have improved the quality of life of affected individuals.

EPIDEMIOLOGY

MS affects approximately 2.3 million people worldwide[2] and is usually diagnosed between 15 and 50 years of age, with a peak incidence occurring in the fourth decade. However, MS can occur in young children and significantly in older adults. While females are afflicted more than males by a ratio of 2.8:1, males usually develop the first signs of MS at a later age and are more likely to develop a progressive form of the disease. The rising incidence of MS in females may be associated with urbanization.[2] Additionally, MS occurs more frequently in Whites of Scandinavian ancestry compared to other ethnic groups.[3]

The factors most important in determining disease risk are geography, environmental influences, age, and genetics (discussed under etiology).[1,4–7] In general, MS is more prevalent above the 37th parallel, although recent studies suggest a waning latitude gradient as demonstrated by a substantial increase in Mediterranean regions. An inverse relationship between MS risk and 25-hydroxyvitamin D levels has been proposed.[8]

ETIOLOGY

The exact cause of MS is unknown but is thought to develop in genetically susceptible individuals exposed to random events and environmental factors that trigger immune-mediated CNS damage. Genetic variation accounts for approximately 30% of the overall disease risk, and more than 100 distinct genetic regions are associated with MS, collectively explaining about one-third of its genetic component.

The familial recurrence rate of MS is approximately 5%, with siblings being the most commonly reported relationship,[6] and monozygotic twins displaying a concordance rate of roughly 25%. Genes that lie within the major histocompatibility complex (MHC), on the sixth chromosome,[1,6] as well as interleukin-2α (IL-2α) and interleukin-7α (IL-7α) receptor genes have been associated with disease risk.[9–11] A genetic-environmental interaction is also reported for the human leukocyte antigen (*HLA*) *DRB1*1501* variant.[12] African Americans are less likely to be diagnosed with MS compared with Whites. However, emerging evidence suggests they are more likely to have a severe disease course and respond less to interferon (IFN) therapy.[13,14] A locus on chromosome 1 may be associated with increased susceptibility in African Americans.[15]

While genetics plays a role in overall disease risk, nongenetic factors such as geography, vitamin D deficiency, smoking, high dietary sodium, circadian disruption, human cytomegalovirus (CMV), the Epstein–Barr virus (EBV), and human herpesvirus-6 have been implicated in MS variably. In genetically susceptible individuals who live in a high-risk area for at least two years before age 15, the risk of MS is high, especially if exposed to an environmental factor. However, if they move from a high- to a low-risk area before age 15, they can acquire the low-risk status, while moving after age 15 can result in persistence of the high-risk status.[6] Smoking cigarettes has been associated with both an increased risk of developing MS as well as more severe progression of disability.[11,16] Excess body weight is also associated with a higher risk of developing MS.[17]

Although clear associations have not been identified, certain viruses might participate in the pathogenesis of MS by initiating or activating autoreactive immune cells in genetically susceptible individuals, leading to subsequent demyelination. Evidence supporting a viral etiology includes increased immunoglobulin G (IgG) synthesis in the CNS and increased viral antibody titers. Epidemiologic studies also indicate pathogen exposure in childhood, suggesting "viral" infections may precipitate exacerbations. In addition, data from both humans and experimental animal models suggest that viral infections with incubation periods cause disease with prolonged myelin destruction and a relapsing-remitting course.[1,18] The greatest evidence supports EBV, as autoreactive T cells could be activated by EBV through molecular mimicry due to sequence similarities between EBV and self-peptides. Other potential mechanisms of demyelination include enhanced breakdown and presentation of self-antigens, expression of viral superantigens, or bystander activation.[19] Antibody titers to Epstein–Barr nuclear antigen (EBNA) complex are higher in patients with MS versus controls and are associated with disease risk depending on sample collection time. Antibodies to specific epitopes within EBNA-1 can result in a 24-fold increased disease risk.[19] In addition, anti-EBNA titers are associated with RRMS, conversion of CIS to clinically definite multiple sclerosis (CDMS, confirmed diagnosis of MS), and with MRI measures such as gadolinium-enhancing lesions, change in T2-lesion volume, as well as the EDSS. Anti-EBNA and antivascular cell adhesion (anti-VCA) titers are also associated with gray matter atrophy in MS.[20] Evidence of active EBV infection, which in time resolves, may lead to EBV-infected B cells being present in postmortem brain tissue of patients diagnosed with MS,[21] however, these findings have not been implicated.[22] Given all of this, most data suggest that EBV exposure is associated with MS development MS but does not support the concept of active EBV or aborting infection as directly causing MS.

PATHOPHYSIOLOGY

An important prominent feature of early-stage MS is immune cell infiltration from the periphery to the CNS, as immune cells enter the CNS parenchyma by crossing the blood−brain barrier, the subarachnoid space, or the choroid plexus across the blood-cerebrospinal fluid (CSF) barrier. Other proposed mechanisms include the “inside out” model where disease progression is a neurodegenerative process, similar to primary-progressive multiple sclerosis (PPMS) and secondary-progressive multiple sclerosis (SPMS), where the antigenic constituents are released from the CNS into the periphery, causing the inflammatory response.

2 Once in the CNS, immune cells promote neurodegeneration by stripping the myelin sheath surrounding CNS axons through an inflammatory, perivenular infiltrate consisting of T and B lymphocytes, macrophages, antibodies, and complement.[18] Demyelination renders axons susceptible to damage, which becomes irreversible when they are severed. Irreversible axonal damage correlates with disability and can be visualized as hypointense lesions, or “black holes,” on T1-weighted MRI.[23,24]

Peripheral immune cells, along with activated CNS-resident microglia and astrocytes, promote demyelination and oligodendrocyte, and neuroaxonal injury. This is mediated through direct cell contact and the actions of soluble inflammatory and neurotoxic mediators; however, the exact trigger for T-cell activation in the periphery remains unclear, but T cells in MS patients recognize myelin basic protein (MBP), proteolipid protein, myelin oligodendrocyte glycoprotein, and myelin-associated glycoprotein. T-helper subtypes can be either pathogenic or protective in MS. One theory holds that specific T-cell subsets are not terminally differentiated but instead engender a level of plasticity that allows for their conversion from pathogenic to protective and vice versa under certain conditions (Fig. 74-1).[25]

FIGURE 74-1

Upon interaction with an antigen-laden APC and specific cytokines, the innate T cells undergo differentiation into a few lineages (subtypes). Four subtypes significant for MS pathophysiology are illustrated here (Th1, Th2, Th17, and Treg). Th1 and Th17 are proinflammatory, Th2 is anti-inflammatory, and Treg is regulatory. Th1 and Th2 are mutually suppressive and are relatively stable differentiated subtypes. In contrast, Th17 and Treg subtypes exhibit “plasticity” in that they can undergo phenotypic conversion to another T-cell subtype (Th1 or Th2) in the presence of specific cytokine conditions. This plasticity of Th17 and Treg is the immunologic basis for development of therapeutic agents to favor the production of suitable Th subtypes for combating microbial invasion and also concurrently achieving neurocellular recovery after an infection.[25] (APC, antigen presenting cell; Th, T-helper cell)

A new concept of T-cell entry into the CNS suggests that the initial lymphocyte invasion may proceed through the ventricles toward the choroid plexus along a gradient that attracts activated Th17 (T-helper) cells.[26] The actual mediator of myelin and axonal destruction has not been established but may reflect a combination of macrophages, antibodies, destructive cytokines, and reactive oxygen intermediates. In patients with stable or mild disease, an increase in the number of cells that express messenger RNA (mRNA) for transforming growth factor-β (TGF-β) and interleukin-10 (IL-10) has been found compared with patients with severe disease. Conversely, a reduction in the number of T-regulatory (Treg) cells, which exhibit suppressor activity, is also associated with active MS and can be found in patients with progressive disease. It should be noted that ratios between various T cells (Treg ratios) do not always correlate with disease activity and that experimental evidence associates high 25-hydroxyvitamin D levels with improved Treg function, favoring the Th2 phenotype in the Th1/Th2 balance.[27] Finally, an immunological hallmark of MS is the intrathecal synthesis of multiple immunoglobulin clones with uncertainty regarding the antigen(s) against which they are directed.[28] Therefore, the complex interplay of various cells, antibodies, and cytokines remains to be elucidated.

It is well accepted that MS lesions are heterogeneous, which may be due to differences in the stage of evolution of the lesions over time, differences in underlying immunopathogenesis, or a combination. Acute lesions show demyelination and axonal destruction with lymphocytic activity consistent with an inflammatory state. In contrast, chronic lesions display less inflammatory lymphocytes with active remyelination.[18] As the disease progresses, immune cell infiltration wanes, perhaps due to adaptive immune cell exhaustion from chronic antigen exposure. However, chronic CNS-intrinsic inflammation and neurodegeneration continue independent of peripheral immune activation. Consequently, meningeal tertiary lymphoid-like structures, which have been documented explicitly in secondary progressive disease, may contribute to late-stage inflammation in patients with this form of MS. In general, the relapsing phases of MS are more inflammatory[29] compared to the progressive forms of MS, where you see more neurodegeneration leading to long-term disability.

Although traditional descriptions focus on the white matter as the sole location of MS lesions, recent studies have identified cortical and subcortical gray matter lesions both pathologically[30] and radiographically.[31] In addition, a subset of patients with progressive MS are noted to have abnormalities consistent with B-cell follicles in the meninges.[32]

Just as the full dimensions of the neuropathology are uncertain, so is the pathogenesis of the MS lesion. However, substantial evidence suggests an autoimmune process directed against myelin and oligodendrocytes, the cells that make myelin[18] (Fig. 74-2).

FIGURE 74-2

Autoimmune theory of the pathogenesis of multiple sclerosis (MS). In MS, the immunogenic cells tend to be more myelin-reactive, and these T cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells ($CD4^+$) appear to be critical initiators of myelin destruction in MS. These autoreactive $CD4^+$ cells, especially of the T-helper cell type 1 (Th1) subtype, are activated in the periphery, perhaps following a viral infection. The activation of T- and B-cells requires two signals. The first signal is the interaction between MHC and APC (macrophage, dendritic cell, and B cell). The second signal consists of the binding between B7 on the APC and CD28 on the T cell for T-cell activation. Similarly, CD40 expressed on APCs and CD40L expressed on T cells interact with signaling the proliferation of B cells within the blood–brain barrier following the entry to T cells. The T cells in the periphery express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood –brain barrier. The activated T cells also produce MMP that help create openings in the blood-−−brain barrier, allowing entry of the activated T cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (INF-γ), which further create openings in the blood–brain barrier, allowing entry of B cells, complement, macrophages, and antibodies. The T cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing the production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of $CD4^+$, $CD8^+$, and Th1 cells.[9] New pathogenic mechanisms involve, but are not limited to, receptor-ligand–mediated T-cell entry via choroid plexus (CCR6-CCL20 axis),[26] coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75 or TROY complex, Jagged-Notch signaling). CLINICAL PRESENTATION

CLINICAL PRESENTATION: Multiple Sclerosis

General

- Most patients with MS present with nonspecific complaints.

Primary Symptoms/Signs

- Visual complaints/optic neuritis
- Gait problems and falls
- Paresthesias
- Pain
- Spasticity
- Weakness
- Ataxia
- Speech difficulty
- Psychological changes
- Cognitive changes
- Fatigue
- Bowel/bladder dysfunction
- Sexual dysfunction
- Tremor

Laboratory Tests

- MS is a diagnosis of exclusion
- MRI
- CSF studies
- Evoked potentials

Secondary Symptoms

- Recurrent UTIs
- Urinary calculi
- Decubiti and osteomyelitis
- Osteoporosis
- Respiratory infections
- Poor nutrition
- Depression

Tertiary Symptoms

- Financial problems
- Personal/social problems
- Vocational problems
- Emotional problem

3 The clinical presentation of MS is extremely variable among patients and over time and is impacted by multiple external factors. The signs and symptoms are divided into three categories. Primary symptoms are a direct consequence of conduction disturbances produced by demyelination and axonal damage and reflect the damaged CNS area. Secondary symptoms are complications resulting from primary symptoms; for example, urinary retention, a primary symptom, can lead to frequent urinary tract infections (UTIs), a secondary symptom. Lastly, tertiary symptoms relate to the effect of the disease on the patient's everyday life.[33]

The clinical course of CDMS is classified into three categories: (1) RRMS, (2) SPMS, and (3) PPMS.[34] At symptom onset, about 85% of patients have relapses/exacerbations, with new symptoms lasting at least 24 hours and separated from other new symptoms by at least 30 days, followed by complete or incomplete remission. Exacerbations are referred to as relapses or attacks. This course is called RRMS, which is characterized by CNS inflammation. The first clinical presentation of RRMS is typically CIS, which is not a definite form of MS. During the RRMS phase, new brain MRI lesions correlate with clinical attacks, but typically, there are more new MRI lesions than new clinical symptoms. In RRMS patients, attack frequency tends to decrease over time and becomes independent of the development of progressive disabilities.[35] Neurologic recovery following an exacerbation is often quite good early in the disease course, but recovery following repeated relapses is not as complete. A new concept of a radiologically isolated syndrome (RIS) refers to individuals who have an MRI scan done for other reasons (e.g., headache) and have radiological signs suggestive of MS. This is not a form of definite MS; however, over time, a percentage of these patients convert to RRMS.[36] When to start DMT remains unclear and varies by practice.

Approximately 10% to 20% of RRMS patients have a benign course (a retrospective diagnosis), characterized by few relapses that are often sensory in nature with minimal disability over time. Most RRMS patients (not with benign disease) eventually enter a progressive phase, referred to as SPMS, in which attacks and remissions are challenging to identify. Disability tends to accumulate more significantly during this phase of the illness. Additionally, new brain MRI lesions, especially those only seen with contrast media, are less common, and brain atrophy and T1 holes increase.[37]

4 Approximately 15% of patients never have discrete phases of attacks and remissions but rather have progressive disease from the outset, known as PPMS. These patients will have symptoms, especially spastic paraparesis, that may or may not worsen rapidly over time and accrue progressively more disability. Patients with PPMS are often diagnosed at later ages, with the number of males roughly equal to females. In general, PPMS patients tend to have a worse prognosis than those initially presenting with RRMS, although progression is variable.[38] A significant portion of patients with PPMS do not receive benefits from studied therapies, although ocrelizumab (Ocrevus) is FDA approved for PPMS.[39] Both PPMS and SPMS are characterized as neurodegenerative processes. Previously, a small percentage of patients were classified as having a mixture of both progression and relapses, referred to as progressive-relapsing multiple sclerosis (PRMS), but since they are generally treated as relapsing patients, this nomenclature is no longer used.

The most widely used clinical rating scale is the EDSS, which uses a numerical value ranging from 0 (no disability) to 10 (death) to evaluate neurologic functions.[40] However, this scale is relatively insensitive to clinical changes not involving impairment of ambulation, such as fatigue, cognition, and affect. Other tools, such as the multiple sclerosis functional composite (MSFC), are being evaluated as a more sensitive measure for changes in MS-related disability over time.[41] Increasingly, MRI is used as an index of both disease activity and progression[18] with new lesions appearance or changes in lesion number, size, and volume used as outcome measures in research studies. Optical coherence tomography measures the retinal neural fiber layer thickness and may also be a measurable sign of pathological progression over time.[42]

The unpredictable nature of MS makes it impossible to anticipate exacerbations. However, certain factors, including infections, heat (including fever), sleep deprivation, stress, malnutrition, anemia, concurrent organ dysfunction, exertion, and childbirth, may aggravate symptoms or lead to an attack. Interestingly, patients experience a significant reduction in relapses during the third trimester of pregnancy, followed by a relative increase postpartum.[43]

Between 60% and 80% of individuals diagnosed with MS have been reported to be sensitive to environmental heat, as temperature influences nerve impulses that are blocked or slowed down in a damaged nerve. Clinically, increased body temperature might worsen previous neurological deficits, including fatigue and decreased muscular endurance. Blurred vision, known as Uhthoff's phenomenon, is caused by increased body temperature due to physical exercise or physical restraint; however, these signs and symptoms improve or disappear after temperature normalization.

Multiple sclerosis does not directly diminish life expectancy. However, the development of secondary complications such as pneumonia or septicemia (secondary to aspiration in those with swallowing difficulties, decubitus ulcers, or UTIs), or rapid progression of primary lesions affecting respiratory function, can lead to a shorter than expected life span. Most life span decreases are seen in patients with rapidly progressive disease. Suicide rates in MS patients have been reported to be significantly higher than that seen in the general population.[44] The clinical and demographic factors used to predict prognosis are listed in Table 74-6.[7,42]

Diagnosis

⑤ Multiple sclerosis is a diagnosis of exclusion as symptoms can frequently be attributed to other neurologic diseases, just as many syndromes can mimic MS. The diagnosis remains primarily a clinical one that requires demonstration of "lesions separated in space and time." This terminology refers to the occurrence of at least two episodes of neurologic disturbance, which reflect specific sites of CNS damage that cannot be explained by other mechanisms.[47] The McDonald criteria, established by an international panel of MS experts,[47] allow for three diagnostic categories which include (1) MS, (2) possible MS (for those individuals at high risk of developing MS), and (3) not MS. These criteria aid in earlier diagnosis compared to older criteria,[45] as they may be somewhat more sensitive and equally specific.[46,48,49] Key to diagnosis is an MRI which is endorsed by the American Association of Neurology consensus panel.[50] In addition to brain MRI lesions, CSF abnormalities, and visual-evoked potential (VEP), studies may be substitutes for clinical lesions in defining "separated in space and time." The 2017 updated McDonald Criteria allow for an earlier diagnosis in patients with CIS to establish "dissemination in space and time" with a single MRI.[47] Therefore, patients only need to have lesions in different CNS areas with at least one enhancing lesion that correlates with clinical symptomatology to fulfill these criteria and be diagnosed with CDMS. As an example, several immunotherapies are US FDA-approved for use after a single attack (CIS) of demyelination in the context of an appropriately abnormal brain MRI.

Laboratory Studies

To date, there are no tests specific for MS but rather, evidence is gathered through (1) MRI of the brain and spine,[50,51] (2) CSF evaluation examining for increased oligoclonal bands and increased IgG, (3) evoked potentials,[45,47] and (4) optic coherence tomography.[52] These should all be used in conjunction with the physical examination and history in establishing the diagnosis. Of these tests, MRI is the most valuable diagnostic tool as the brain and spine images reflect damage characteristic of MS plaques in multiple areas of the CNS. Therefore, MRI is the preferred technique for establishing a diagnosis, prognosis, and determining disease progression. Optic neuritis, a lesion or lesions on the optic nerve, is a common first symptom of MS. A more significant number of T2-weighted lesions (called *T2 burden of disease*) on MRI following optic neuritis or CIS appears to correlate with the development of disability and progression to CDMS.[51] Through the use of the contrast agent gadolinium, new lesions and disruptions of the blood−brain barrier can be determined and are associated with early conversion to CDMS in CIS patients.[51,53] However, these gadolinium-enhanced lesions do not correlate well with disability progression when examined over time, while brain atrophy, even early in the course of the illness, probably correlates better.[50]

Differential Diagnosis

Because many disorders can mimic MS, most patients are first screened with blood tests for rheumatologic, collagen-vascular, infectious, and sometimes inherited metabolic diseases. Additionally, electromyography may help in diagnosing amyotrophic lateral sclerosis and neuropathies.

Magnetic resonance imaging is used to rule out tumors and cervical spondylosis and may also lead to MS evaluations for many patients with little or no clinical history of MS. While some patients may have MRI scans suggestive of MS (so-called RIS), most have nonspecific scans with identifiable causes for their symptoms, including age greater than 50 years, hypertension, and migraine.[54] The use of established criteria for distinguishing MS lesions from other etiologies enhances diagnostic accuracy.

TREATMENT

Treatment of MS falls into three broad categories: (1) treatment of exacerbations, (2) disease-modifying therapies (DMTs), and (3) symptomatic therapies. While treatment of exacerbations will shorten the duration and possibly decrease the severity of the attack, the DMTs can alter the course of the illness and diminish progressive disability over time; however, symptomatic disease management is of utmost importance to maintain quality of life. Although different treatment modalities have been studied in the last 30 years, older trials are flawed, and as such, there are no universally accepted treatment algorithms for MS. In 2018 the American Academy of Neurology (AAN) released DMT practice guidelines for adult MS. One potential algorithm for the immunotherapy of CDMS is shown in Fig. 74-3.[55] The Consortium of Multiple Sclerosis Centers also put out guidelines on treatment selection based on patient-specific factors.[56] However, treatment recommendations often vary among clinicians and centers, and decisions are frequently based on the wishes and goals of individual patients.

• Consider B cell therapies (rituximab or ocrelizumab)
• Consider alemtuzumab if B cell therapies fail, intolerable or inaccessible
• Consider natalizumab therapy with intense PML surveillance
• Consider experimental Rx

*Mitoxantrone is approved, but not used due to risk of secondary leukemia.
*Progression: any new relapses, accumulation of disability, and/or new or enlarging lesions.

Desired Outcomes

The main treatment goals are to improve the overall quality of life, maintain employment, and minimize long-term disability for MS patients. Disease-related treatment goals include reducing exacerbations or relapses, decreasing the number of white matter lesions and black holes on MRI, averting brain atrophy, and ultimately halting disease progression. Both treatment and disease-related goals can be obtained with early disease recognition and immediate utilization of FDA-approved DMTs.

General Approach to Treatment

The severity of symptoms at initial presentation will determine whether an induction or escalation algorithm is assigned to an individual patient. When currently available FDA-approved medications do not alter natural disease progression, investigational agents or non–FDA-approved medications, such as rituximab, may be used. The use of escalation approaches early in the disease course with safer yet partially effective medications is thought to be helpful.

MS unfortunately often affects individuals in their most productive years of life. Therefore, practitioners must help patients set realistic expectations over their lifetime by developing long-term treatment and management plans. Throughout this illness, patients are likely to acquire secondary and tertiary MS symptoms. In clinical trials, high nonadherence rates are a factor in treatment failure. Nonadherence may occur due to perceived lack of treatment benefit, cost, adverse effects, depression occurrence, complicated dosing, and/or undesirable routes of administration (eg, subcutaneous, intramuscular injection, intravenous [IV]). Figure 74-3 represents a clinical algorithm for the treatment of MS.[55]

Nonpharmacologic Therapy

Medications are the primary mainstay of MS treatment. Still, patients may find occupational therapy beneficial to improve the activities of daily living or learn new techniques or tools to accomplish these tasks and remain active. Furthermore, physical therapy may improve muscle strength to improve their gait and balance, and stretching exercises reduce muscle spasms or help mobility through aids such as canes or walkers.

Pharmacologic Therapy

Treatment of Exacerbation

⑥ Exacerbations are the hallmark of early RRMS. Although recovery after relapses is generally complete, continued relapses over time may be associated with a substantial accumulation of disability. Frequent relapses (more than three relapses per year in the first two years after diagnosis) have shown a consistent positive correlation with developing neurological disability later. However, mild exacerbations that do not produce functional decline may not require treatment. Therefore, decisions to treat relapses are usually substantiated by patient expectations, prior experience with corticosteroids, and predicted course of recovery. Accepted treatment indications for relapses that are (1) mono- or polysymptomatic presentations; (2) relapses that localize to the optic nerve, spinal cord, or brainstem; (3) those with functional limitations that affect activities of daily living; and (4) symptoms that worsen over a 2-week period. An IV injection of high-dose corticosteroids such as methylprednisolone is recommended by the AAN when functional ability is affected.[55] While corticosteroid mechanism of action in MS is unknown, they may improve recovery by decreasing edema in the area of demyelination. In particular intravenous methylprednisolone can shorten the exacerbation duration and also potentially delay repeat attacks for up to two years after optic neuritis,[55] although it does not definitively affect disease progression.[57]

According to clinical response, methylprednisolone doses range from 500 to 1,000 mg/day, given IV for 3 to (rarely) 10 days. In initiated within 2 weeks of symptom onset, the functional recovery after an exacerbation is more rapid, with improvement usually beginning after 3 to 5 days. Short-term steroid use is often accompanied by sleep disturbance, a metallic taste in the mouth, and rarely gastrointestinal (GI) upset. Patients with diabetes mellitus or a predilection to diabetes mellitus may have significant elevations of blood sugar, requiring the use of insulin. Intravenous methylprednisolone therapy is associated with acne and fungal infections, mood alteration, and, rarely, GI hemorrhage (especially in hospitalized patients or in those taking aspirin) when administered for longer durations. Equipotent doses of oral prednisone or dexamethasone can be substituted for IV methylprednisolone, although dexamethasone use is not well supported in the literature. Although adrenocorticotropic hormone (ACTH) is the only FDA-approved agent for MS exacerbation treatment, it is rarely used due to cost and availability.

A small number who experience a relapse of MS will have more severe attacks, manifested by hemiplegia, paraplegia, or quadriplegia. If improvement with aggressive steroid therapy is not seen, plasma exchange (PLEX) every other day for seven treatments can be beneficial for approximately 40% of patients, or intravenous immunoglobulin can be given.

A “pseudoexacerbation” must be ruled out before exacerbation treatment is initiated or DMTs are altered. Within this context, a “pseudoexacerbattion” occurs when symptoms occur for less than 24 hours or are precipitated by something other than the natural course of the disease, such as heat, infections (eg, UTIs), or stress (emotional or physical).

Disease-Modifying Therapy

Table 74-1 shows the indications and dosing of DMTs. medications used to treat MS are either immunomodulatory (ie, alter the immune signals without cytotoxic effect or bone marrow suppression) or immunosuppressive (ie, alter the immune system through a direct cytotoxic activity or bone marrow suppression). These drugs, however, have a higher risk-to-benefit ratio based on their safety profile when used later on in therapy.[29] The current FDA-approved first-generation therapies are self-injected medications that decrease annualized relapse rate by about 30% and decrease the formation of new white matter lesions. These include four interferon (IFN) formulations and glatiramer acetate (a non-IFN). The first-generation DMTs are not immediately effective for symptoms, but rather their efficacy may be seen approximately one to two years after starting therapy. In addition to the first-generation DMTs, the FDA has also approved ocrelizumab, natalizumab, mitoxantrone, fingolimod, siponimod, ozanimod, ponesimod, teriflunomide, dimethyl fumarate, diroximel fumarate, monomethyl fumarate, cladribine, ofatumumab, and alemtuzumab for the treatment of relapsing forms of MS. Ocrelizumab is also FDA-approved for PPMS, and mitoxantrone has an additional FDA indication for progressive or worsening MS. These therapies are considered specialty medications and are only available through specialty pharmacies at a yearly cost of upwards of $100,000. This cost does not include nursing, pharmacy, and technical fees, especially for the infusion medications that require administration in an outpatient facility under medical supervision.

CIS, clinically isolated syndrome; IM, intramuscular; PRMS, primary relapsing multiple sclerosis; REMS, Risk Evaluation and Mitigation Strategy; RRMS, relapsing-remitting multiple sclerosis; SPMS, secondary progressive multiple sclerosis; SQ, subcutaneous; IU, international units.[58,59]

8 In some patients with poor prognostic factors and poor clinical presentation, ocrelizumab, natalizumab, fingolimod, teriflunomide, and dimethyl fumarate may be prescribed as initially instead of starting a first-generation DMT associated with less serious side-effect risk. This practice would be considered an induction therapy, where all therapeutic efforts concentrate in the early phases of the disease.

The efficacy of the DMTs may vary considerably between individual patients and for any given patient at different time points. Moreover, patients may have different adverse medication effects or risk tolerance and preferences regarding the administration route. Therefore, access to the full range of therapeutic options is critical for decision making between patients and their clinicians. Table 74-2 outlines adverse medication reactions and monitoring parameters of DMTs.

Interferon-β_{1b} and Interferon-β_{1a}

IFN-β_{1b} (Betaseron, Extavia) was the first agent proven to favorably alter the natural course of the illness (Table 74-7).[57] Although its mechanism of action is unknown, it does exert immunomodulating properties, including augmentation of suppressor cell function, reduced IFN-γ secretion by activated lymphocytes, its macrophage-activating effect, and its ability to downregulate the expression of IFN-γ-induced class II MHC gene products on antigen-presenting glial cells. Additionally, IFN suppresses T-cell proliferation and may decrease blood−brain barrier permeability by reducing matrix metalloproteinases.[57] IFN-β also increases the production of regulatory CD56 (bright) natural killer cells and Treg cells.[60] In general, all IFNs exert these actions in the periphery and at the blood−brain barrier level.

TABLE 74-7

Evidenced-Based Recommendations for Disease-Modifying Treatment of Multiple Sclerosis

Recommendations	Recommendation Grades*
Interferon-β	
• Interferon-β has been shown to reduce attack rates in patients with MS or those with CIS who are at high risk of developing MS	A-I
• It is appropriate to consider IFN-β for any patient with clinically definite MS or who already has RRMS or SPMS and is still experiencing relapses	A-I
• The effectiveness of IFN-β in patients with SPMS but without relapses is uncertain	U-I
• Route of administration of IFN-β products is probably not clinically important with regards to efficacy; however, the side-effect profile does differ	B-II
• Rate of production of neutralizing antibodies is probably less with IFN-β_{1a} than with IFN- β_{1b}	B-I

- Presence of neutralizing antibodies may be associated with a reduction in the clinical effectiveness of IFN-β treatment	C-I
Glatiramer acetate	
- Glatiramer acetate has been shown to reduce the attack rate in patients with RRMS	A-I
- Treatment with glatiramer acetate may slow sustained disability progression in RRMS	C-I
Mitoxantrone	
- Mitoxantrone probably reduces the attack rate in patients with relapsing forms of MS	B-II, III
- Mitoxantrone may have a beneficial effect on disease progression in MS	C-II, III
Natalizumab	
- Natalizumab decreases clinical relapse rate, gadolinium-enhancing lesions, and new T2 lesions	A-I
- Natalizumab in RRMS positively changes measures of disease severity such as EDSS progression rate and changes lesions on MRI in RRMS	A-I
Ocrelizumab	
- Ocrelizumab in PPMS is shown to decrease confirmed disability progression, lessen worsening of timed 25-ft (~7.5 m) walk, decrease T2-weighted MRI lesions volume by 3.5%, and percentage of brain volume loss by 0.90%	A-I
- Ocrelizumab in RRMS positively changes measures of disease severity such as EDSS progression rate and changes lesions on MRI in RRMS	A-I

*Strength of recommendations: A: established; B: probable; C: possible; U: inadequate data to support recommendation.

CIS, clinically isolated syndrome; RCT, randomized controlled trial; RRMS, relapsing-remitting multiple sclerosis; SPMS, secondary-progressive multiple sclerosis.

Quality of evidence: Class I, evidence from one or more prospective, randomized, controlled clinical trial; Class II, evidence from cohort or RCT not meeting criteria for class I; Class III, evidence from other controlled trials; Class IV, evidence from uncontrolled studies, case reports, case series, or expert opinion.

Data from References 60,62.

IFN-β_{1b} is a nonglycosylated synthetic analog of recombinant IFN-β produced in *Escherichia coli*. It is administered subcutaneously every other day at a dose of 250 mcg (8 million international units). Clinical trials have demonstrated that at these doses, IFN-β_{1b} significantly reduces the annual relapse rate and MRI burden of disease compared with placebo; however, no significant differences between the IFN and placebo were noted with respect to clinical disability.[60] Betaseron is packaged in partially premixed syringes that do not require refrigeration and can be used with an autoinjector. In 2009, Extavia was approved; however, this is the same medicinal product as Betaseron.

IFN-β_{1a} (Avonex, Rebif) is a natural-sequence glycosylated IFN produced in Chinese hamster ovary cells. Avonex is administered as a 30-mcg dose (6 million international units) intramuscularly once weekly and Rebif is given as either 22 or 44-mcg subcutaneously three times weekly. Both are supplied in a 0.5-mL prefilled syringe which should be refrigerated but is stable at room temperature for 30 days. Rebif may have lower immunogenicity and a slightly better side-effect profile than Avonex.[61]

Patients receiving IFN-β_{1a} (Avonex) for two years demonstrated statistically significant reductions in annual relapse rates (by approximately one-third), as well as disease progression (defined as a confirmed decrease of one point on the EDSS), compared to placebo.[61] Patients receiving Avonex had significantly fewer new enhancing lesions on MRI compared with placebo, and similar results were seen with the higher dose of (44 mcg) of Rebif.[61] Other studies reveal Avonex's significant effects on slowing brain atrophy[62] and the progression of cognitive decline.[63] Therefore, these observations show that IFN-β possesses significant disease-modifying activity.

Pegylated IFN-β_{1a} (Plegridy) is FDA-approved for relapsing forms of MS. The attachment of polyethylene glycol (PEG) polymer chains to the interferon molecules result in a longer half-life and allows for less frequent dosing, as it is given by subcutaneous injections once every two weeks. Plegridy is associated with a significant reduction in annualized relapse rates (35.6%), new MRI lesions, risk of disability progression compared to placebo.[64]

All of the IFN's have similar adverse medication reactions, and CBCs, platelets, and LFTs should be documented at baseline, after one month of therapy, every three months for one year, and every six months thereafter. A small percentage of patients develop depressed blood cell counts that usually respond to therapy discontinuation. Transient elevations in liver enzymes can also be seen, which respond to treatment discontinuation. However, rare cases of liver failure requiring transplantation have been reported, which have resulted in package insert modifications for all IFN-β products to reflect this risk. Other more common adverse effects include injection-site redness and swelling, menstrual irregularities, and rarely injection-site necrosis. Injection-site reactions with IFN-β_{1b} are probably worse and can occur at any time. They can be lessened by rotating the injection site, using an autoinjector, using topical lidocaine, or applying ice before and after the injection. In addition, injecting the medications at body temperature (place under armpits to warm) will decrease injection-site pain.

Flu-like symptoms (eg, fever, chills, and myalgias) are seen in most patients and typically occur up to 24 hours after injection. These symptoms usually abate within one to three months after starting the injections; however, for some patients, they may persist. To alleviate these flu-like symptoms, patients may try taking the injection at bedtime to sleep through the most bothersome symptoms. They may also use a nonsteroidal anti-inflammatory agent or acetaminophen before and regularly for 24 hours after IFN-β administration. Using one-quarter or one-half the standard dose, with an increase to the full dosage over one to two months, is also beneficial in reducing flu-like adverse medication reactions.[65] Lastly, a short burst of oral prednisone can alleviate some adverse effects as this may suppress the transient immune activation that can occur following the introduction of IFN-β.[65]

Less common adverse medication reactions include transient shortness of breath or tachycardia, thyroid dysfunction, and neutralizing antibodies. All the IFNs, but especially IFN-β_{1b}, can produce depressive symptoms. Therefore clinicians must monitor all patients carefully depressive symptoms and monitor closely for suicide risk. Most patients will not see MS symptom improvement when taking IFNs, and many will experience adverse medication reactions; thus, adherence is a significant issue.

Finally, safety data on IFN-β in pregnancy and lactation is lacking, and abortifacient activity in primates has been noted. Until adequate safety data are available, individuals who are biologically female and are able to get pregnant should be counseled to use appropriate contraception while using these products.

Glatiramer Acetate (Copaxone)

Glatiramer acetate (formerly known as copolymer-1) is a synthetic polypeptide consisting of L-alanine, L-glutamic acid, L-lysine, and L-tyrosine. Its precise mechanism of action is unknown, but it appears to mimic the antigenic properties of myelin basic protein (MBP).[66] This agent may act directly to MHC class II receptors and inhibit the binding of MBP peptides to T-cell receptor complexes.[66] Glatiramer acetate induces Th2 (anti-inflammatory) lymphocytes in experimental allergic encephalomyelitis,[66] which is thought to contribute to "bystander" suppression at the site of the MS lesion, resulting in reduced inflammation, demyelination, and axonal damage.[57] However, it may also suppress T-cell activation and recent studies suggest it has a neuroprotective effect by inducing brain-derived neurotrophic factor.[67]

Given subcutaneously, as a daily 20-mg or three times weekly 40-mg dose, glatiramer acetate, or its generic biosimilar, Glatopa appear to have a relatively mild adverse effect profile with mild injection site pain and pruritus being most common. Approximately 10% of patients experience a one-time transient reaction consisting of chest tightness, flushing, and dyspnea beginning several minutes after injection and usually lasting no longer than 20 minutes. This postinjection reaction occurs with any dose and is not limited to the first injection. If patients have no history or evidence of coronary artery disease, they may be assured these reactions are almost always self-limited and benign.

Glatiramer acetate has demonstrated significant reductions in mean annual relapse rate (approximately 29%), comparable with the IFNs and may slow the progression of disability in patients with RRMS.[65] It also delays the development of T1 holes on brain MRIs.[68] Long-term uncontrolled data show that it remains safe and effective for over 10 years.[69] Glatiramer acetate needs to be stored in the refrigerator but can be kept at room temperature for up to 1 week.

The FDA-approved Copaxone for the treatment of RRMS based on a placebo-controlled trial in treatment-naive patients that demonstrated significant reductions in mean annual relapse rate (approximately 34%), number of new T1 and T2 lesions, and similar safety profiles.[70] Recent studies show favorable adverse medication effects and convenience profiles, with comparable efficacy when patients were switched from glatiramer acetate 20 mg daily to 40 mg three times weekly.[71]

Natalizumab (Tysabri)

Natalizumab is a partially humanized monoclonal antibody directed at the cell surface adhesion molecule $\alpha_4\beta$-integrin (also known as very-late antigen 1, VLA-1). It works by attaching to VLA-1 and blocking its ability to interact with its ligand on CNS endothelium vascular cell adhesion molecule 1 (VCAM-1), resulting in activated lymphocytes that are denied entry past the blood−brain barrier.

Natalizumab significantly reduces the number of new gadolinium-enhancing lesions by more than 90%, diminished relapses by 60%.[72] Compared to placebo, natalizumab also significantly delayed disability progression.[73] When added to IFN-β_{1a} (Avonex), natalizumab reduced relapse rates by more than 50% and gadolinium-enhancing lesions by 84%, compared to patients who continued with IFN-β_{1a} alone.[74] In these trials, natalizumab was infused IV every four weeks and was relatively well tolerated, although approximately 1% of patients developed infusion reactions, and 6% developed neutralizing antibodies that diminished the efficacy of the medication.

Natalizumab is FDA approved for use in relapsing forms of MS. Shortly after its approval, three patients were reported to have contracted progressive multifocal leukoencephalopathy (PML), a rare brain infection most commonly seen in patients with human immunodeficiency virus.[75–77] In response, the FDA issued a black-box warning about PML and required enrollment in a Risk Evaluation and Mitigation Strategy (REMS) program called TOUCH. While the estimated risk for PML is low, it is high compared to other MS treatments.[78] As of December 2017, natalizumab is correlated to 756 PML cases, with three factors impacting the overall risk; (1) duration of treatment (24 months or longer); (2) prior use of immunosuppressive therapies (mycophenolate mofetil, alemtuzumab, efalizumab, and rituximab); and (3) a history of anti-John Cunningham virus (JCV) antibodies.[79,80] Current recommendations are to screen patients at baseline and every 6 months with a JCV test while receiving natalizumab.[81] A two-step enzyme-linked immunosorbent assay (ELISA, STRATIFY TEST) is available for the qualitative detection of serum antibodies to the JCV, offering a false-negative rate of 2.5%.[79,80]

For those patients developing PML, a plasma exchange (PLEX) can help rapidly clear the medication from the blood.[82] An acute syndrome, referred to as immune reconstitution inflammatory syndrome (IRIS), is associated with acute neurological deterioration after PLEX, requiring high-dose steroids.[83] Natalizumab is generally reserved for patients with highly active disease or those who have not responded to more well-tolerated agents, given its risk profile.

Sphingosine-1-Phosphate Receptor Agonists (Fingolimod, Siponimod, Ozanimod, Ponesimod)

Fingolimod (Gilenya) was the first oral DMT approved for MS. It mechanistically acts as a sphingosine 1-phosphate (S1P) receptor agonist and exhibits its immunosuppressant properties by sequestering circulating lymphocytes into secondary lymphoid organs. Additionally, fingolimod also reduces the infiltration of T lymphocytes and macrophages into the CNS, resulting in neuroprotective effects. In clinical trials, it decreased annualized relapse rates by approximately 52% compared to IFN-β_{1a}, and 92% of patients were free of gadolinium-enhancing lesions after seven years of continuous therapy.

However, this data was obtained using the 1.25 mg dose, which is different from the FDA-approved dose of 0.5 mg once daily. Fingolimod is the first DMT to have a pediatric indication for children age ten years and older. Siponimod (Mayzent) and Ozanimod (Zeposia) bind to S1P receptors 1 and 5 with higher affinity and Ponesimod (Ponvory) binds to the S1P receptor only, which makes these agents more selective than fingolimod, which binds to receptors 1, 3, 4, and 5.

Fingolimod is associated with pronounced first-dose bradycardia. Other rarer adverse medication reactions include bradyarrhythmia or atrioventricular block, infections, macular edema, a decrease in forced expiratory volume over 1 second in patients with previously compromised lung function, liver enzyme elevation, sustained 1 to 2 mm Hg increases in systolic and diastolic blood pressure, and lymphoma. All patients starting fingolimod should be monitored for signs of bradycardia for six hours after the first dose, including hourly pulse and blood pressure measurement. Additionally, ECG monitoring should start before dosing and continue until the end of the observation period or until all symptoms resolve. For patients at higher risk, this monitoring should continue longer than 6 hours, and in some cases, continue overnight. A new 6-hour observation period is required for patients who have discontinued and wish to restart therapy, however, this requirement varies depending on the days of missed treatment. Furthermore, extended monitoring is recommended for patients with certain preexisting conditions such as QT prolongation or those receiving concomitant medications that slow the heart rate or atrioventricular conduction, cause QT interval prolongation, or have a known risk for torsades. The following class Ia and class III antiarrhythmic agents are contraindicated for concurrent use with fingolimod: quinidine, procainamide, disopyramide, amiodarone, bretylium, sotalol, ibutilide, azimilide, dofetilide, and dronedarone.[84] As of March 2018, PML has also been reported with fingolimod use in eight patients, which was seen after three years of exposure, and independent of natalizumab treatment.[78] Similar adverse events have been experienced in the pediatric population.

Since siponimod, ozanimod, and ponesimod bind more selectively to the S1P receptor, their labeling only requires first-dose observation for high-risk groups.[85,86] Additionally, ponesimod is a 4-hour first-dose observation compared to a 6-hour observation period.[87] Upon starting therapy, a slow titration is required for all three agents. However, siponimod also requires CYP2C9 genotype testing to determine dose adjustments or contraindications. For CYP2C9 genotypes *1/*1, *1/*2, or *2/*2, associated with normal metabolism, no dose adjustments are required. For CYP2C9 genotypes *1/*3 or *2/*3, associated with intermediate metabolism, a dose reduction is necessary, and siponimod is contraindicated for use in patients with a CYP2C9 *3/*3 genotype associated with poor metabolizer status.[85]

Additional monitoring recommendations for S1P receptor modulator use include baseline CBCs, LFTs, ophthalmologic examinations, and ECG in patients with known heart problems. Importantly, ketoconazole can increase the area under the curve of fingolimod by 70%. For patients requiring live vaccine administration (ie, Zostavax, Flumist, Measles, Mumps, and Rubella [MMR], Yellow Fever [YF-VAX]), consider doing so prior to starting fingolimod or waiting two months after discontinuation. Ozanimod should not be coadministered with CYP2C8 inhibitors, BCRP inhibitors, or strong CYP2C8 inducers.[86] Ponesimod leaves the blood in about 1 week if treatment needs to be stopped for any reason. This provides for flexibility if a patient needs vaccines, desires to start family planning, or has any infections that need to be addressed.[87]

Teriflunomide (Aubagio)

Teriflunomide is an oral immunomodulatory agent, the FDA approved for the treatment of relapsing forms of MS. The medication works by inhibiting dihydroorotate dehydrogenase to prevent the proliferation of peripheral lymphocytes (T and B cells). The reduction of activated lymphocytes within the CNS reduces inflammation and demyelination in patients with MS. Teriflunomide is the active metabolite of leflunomide, an agent approved for treating rheumatoid arthritis, and is dosed as 7 or 14 mg orally once daily.

In CDMS patients, teriflunomide (7 or 14mg dose) resulted in a 31% reduction in annualized relapse rates and unique active lesions per MRI scan compared to placebo.[88] Disability progression was also reduced by almost 30% for those receiving 14 mg of teriflunomide daily.[89]

Although teriflunomide is not metabolized by CYP450 enzymes, it inhibits CYP2C8 and induces CYP1A2. This medication is also a substrate for the breast cancer–resistant protein (BCRP); therefore, inhibitors of BCRP (e.g., cyclosporine) may increase serum concentrations of teriflunomide. Additionally, teriflunomide inhibits other organic anion transporters such as OATP1B1 and OAT3; however, the significance of these medication interactions is unknown at this time. Concomitant use of warfarin and teriflunomide resulted in a 25% decrease in the international normalized ratio (INR), necessitating close monitoring. When coadministered with estradiol and levonorgestrel, the mean maximum serum concentration and area under the curve are increased.

Terifluonomide's most common adverse effects are increases in LFTs, alopecia, nausea, diarrhea, influenza, headache, and paresthesia. Recommended monitoring includes monthly LFTs for the first 6 months due to teriflunomide's black-box warning related to hepatotoxicity risk. Additionally, teriflunomide also has a black-box warning for teratogenicity, as animal studies linked oral teriflunomide with fetal malformations and embryo lethality in female rats, as well as reduced sperm count in male rats. Therefore, teriflunomide is contraindicated in pregnancy and in individuals of childbearing potential not using reliable contraception. During therapy or within 2 years after discontinuation, patients who become pregnant should enroll in the Aubagio Pregnancy Registry and consider a cholestyramine washout. Additionally, males may also consider a cholestyramine washout to reduce serum medication levels should their partner's pregnancy be desired, as this medication may remain in the blood for up to 2 years after discontinuation. Teriflunomide may activate tuberculosis, so a negative skin test or treatment of the disease must be documented prior to starting therapy.

Dimethyl Fumarate (Tecfidera), Diroximel Fumarate (Vumerity), and Monomethyl Fumarate (Bafiertam)

Dimethyl fumarate, diroximel fumarate, and monomethyl fumarate true mechanism of action is unknown; however, they are in vitro nicotinic acid receptor agonists and in vivo activators of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway that is involved in the cellular response to oxidative stress. Dimethyl fumarate and diroximel fumarate are both converted to the same active metabolite, monomethyl fumarate. These three DMTs are FDA approved for relapsing forms of MS, including CIS, relapsing-remitting disease, and active secondary progressive disease in adults.

Esterases metabolize dimethyl fumarate in the GI tract, blood, and tissues with no known medication interactions. It is initially dosed at 120 mg (delayed release) orally twice daily. After seven days, the dose is increased to 240 mg (delayed release) orally twice daily. Dimethyl fumarate decreases the annualized relapse rate by 44% to 52%.[90,91] Laboratory monitoring includes a CBC before starting therapy, 6 months later, and then annually. Adverse medication reactions include lymphocytopenia (2%-6%), increased LFTs, and flushing (40%), which are reduced by food intake and dissipate over 1 month. Four cases of PML are attributed to dimethyl fumarate use as of March 2018.[78] Rash, abdominal pain, diarrhea, nausea, and vomiting have also been reported, which decrease over 1 month and respond to symptomatic treatment; however, slowing the dose-escalation may reduce GI adverse medication reactions risk. Dimethyl fumarate has a pregnancy Category C classification.

Diroximel fumarate is dosed at 231 mg twice daily orally, increased to a maintenance dose of 462 mg (administered as two 231 mg capsules) twice daily after 7 days.[92] Monomethyl fumarate is dosed at 95 mg twice daily orally, increased to maintenance dose of 190 mg (administered as two 95 mg capsules) twice daily after 7 days.[93] Flushing associated with these agents can be reduced by coadministration with food or with 325mg of a non-enteric coated aspirin 30 minutes before dosing.[93] Both diroximel fumerate and monomethyl fumarate carry the same monitoring and laboratory recommendations as dimethyl fumarate, including PML risk. These agents also have a lower incidence of gastrointestinal symptoms compared to dimethyl fumarate.[94,95]

Cladribine (Mavenclad)

Cladribine is an oral DMT whose mechanism is thought to impair DNA synthesis, resulting in dose-dependent depletion of both B- and T-lymphocytes. It is a prodrug, activated through phosphorylation to 2-chlorodeoxyadenosine triphosphate (Cd-ATP). It is indicated to treat relapsing forms of MS to include relapsing-remitting disease and active secondary progressive disease in adults. Cladribine has been shown to significantly reduce the annualized relapse rate as 81% of patients in clinical trials did not replase. Additionally, cladribine reduces the time to 3-month confirmed EDSS progression and the median number of active T1 Gd+ lesions and active T2 lesions compared to placebo.[96]

It is administered in two treatment courses, which occur approximately 1 year apart from each other, and consist of two cycles of treatment for a total of four doses over 2 years. The maximum lifetime dose of cladribine is 3.5 mg per kg bodyweight which is 1.75 mg per kg per treatment course. The first treatment course has two cycles, the first dose is started anytime, and the second dose is administered 23-27 days after the first dose of the first course. The second-year treatment course is started approximately 1 year after the start of the first course, and the final dose of treatment should be administered 23 to 27 days after the first dose of the second-year course.[97]

Adverse medication reactions from treatment include increased risk of infection (including Tb, hepatitis B or C, shingles, and PML), liver injury, and heart failure. Cladribine requires a medication guide due to its adverse medication effect profile and increased risk of malignancies and teratogenicity. Treatment monitoring includes cancer screening, CBC, infection screening (including MRI for PML), and liver enzyme tests. It is not indicated for the treatment of CIS due to its severe adverse medication reactions, and therefore should be saved for use in patients who have had an inadequate response or cannot tolerate other DMTs.[97]

Alemtuzumab (Lemtrada)

Alemtuzumab is a humanized monoclonal antibody against CD52, a glycosylphosphatidylinositol–anchored protein consisting of 12 amino acids expressed at high levels on T and B lymphocytes, and to a lesser extent on monocytes, macrophages, and eosinophil granulocytes. Within a few minutes after infusion, alemtuzumab leads to depletion of CD52 positive cells through antibody-dependent cell-mediated cytolysis and complement-dependent cytolysis.

Alemtuzumab is FDA-approved for the therapy of RRMS. Compared to IFN-β_{1a} therapy alemtuzumab demonstrated a 50% reduction in relapses and a significant reduction in the 6-month accumulation of disability.[98,99] Additionally, MRI measures also proved alemtuzumab's superiority with significantly less gadolinium-enhancing lesions, new or enlarging T2 lesions, and brain atrophy.[98] Lastly, significantly more alemtuzumab than IFN-β_{1a}–treated patients were free of any clinical and MRI disease activity. Currently, alemtuzumab therapy is approved for two courses of treatment administered a year apart. In the first course, 12 mg is infused for 5 consecutive days and then for 3 days in the second course.

Alemtuzumab's high efficacy parallels its considerable high risk of infusion-associated reactions (IARs), affecting over 90% of patients.[100] Concomitant corticosteroids, antihistamines, and antipyretic medications can help avoid IARs. Other adverse medication reactions are commonly mild to moderate and consist of headache, rash, pyrexia, and nausea. Respiratory tract and UTIs are also common. During the clinical studies, the incidence of herpes infections led to the recommendation that prophylactic acyclovir treatment be implemented 0 to 4 weeks after alemtuzumab infusion to reduce infection rates significantly. Moreover, there are single case reports of spirochetal gingivitis, pyogenic granuloma, esophageal candidiasis, tuberculosis, and listeria meningitis. Thus, it is best to avoid unpasteurized cheeses while taking this medication.[100] PML has also been reported after the second alemtuzumab cycle; therefore, monitoring is warranted for all patients.[101]

Additional risks seen with alemtuzumab use include secondary autoimmune disease occurring in approximately 30% to 40% of patients, predominantly impairing thyroid function and manifesting as hyperthyroidism, hypothyroidism, goiter, and thyroiditis. There is also a small but serious risk of immune thrombocytopenia (ITP) that can occur post-alemtuzumab administration. Lastly, glomerulonephritis and single cases of autoimmune neutropenia, hemolytic anemia, and type 1 diabetes have been reported.[100] Therefore, extensive monitoring and early intervention allow for appropriate risk management.

Ofatumumab (Kesimpta)

Ofatumumab, is a recombinant human monoclonal immunoglobulin G1 antibody that binds to CD20 expressed B-cells resulting in antibody-dependent cellular cytolysis and complement-mediated lysis. It is indicated for the treatment of relapsing forms of MS, including CIS, RRMS, and active SPMS in adults. Ofatumumab is the only once weekly subcutaneous injection DMT intended for self-administration.

Clinical studies have shown that Ofatumumab results in a significantly lowered annualized relapse rate versus teriflunomide. It also reduces the risk of 3-month confirmed disability progression and the number of T1 Gd+ lesions and T2 lesions. These effects were also seen in subgroup analyses defined by sex, age, body weight, prior nonsteroid MS therapy, and baseline disability and disease activity.[102,103]

The initial dose is 20 mg given at weeks 0, 1, and 2, followed by 20 mg given once a month starting at week 4. Ofatumumab should be given subcutaneously in the abdomen, thigh, or outer upper arm, avoiding any moles, scars, stretch marks, or other irritated or tender skin. The first injection should be administered under the supervision of a healthcare professional. It is available as a Sensoready® pen and prefilled syringes, which are onetime use only. These preparations should be stored in the refrigerator and allowed to reach room temperature for about 15 to 30 minutes prior to administration.

Prior to the first dose, hepatitis B screening and serum immunoglobulins should be performed, as well as the administration of all live or live-attenuated vaccines. The most common adverse medication reactions include upper respiratory tract infection and headache. Other warnings include increased risk of infections (including PML), injection-related reactions, reduction in immunoglobulins, and fetal risk. For these reasons, ofatumumab has a Medication Guide.

Mitoxantrone (Novantrone)

Mitoxantrone, a member of the anthracenedione family, is approved by the FDA for reducing neurologic disability and the frequency of clinical relapses in patients with SPMS (chronic) or worsening RRMS.[104] Based on the clinical trials to date, the best MRI outcomes were seen in relapsing patients.[105] Additionally, clinical trials specifically documenting its effects on slowing MS progression in patients with SPMS have not been done.[104,105] Thus, support for the use of mitoxantrone in this context is lacking.[106]

Mitoxantrone is administered as a brief (5- to 15-minute) IV infusion dosed at 12 mg/m^2 every three months with a maximum allowable lifetime cumulative dose of 140 mg/m^2. Evaluations of left ventricular ejection fraction and ECG are required prior to each dose, and if signs or symptoms of congestive heart failure develop, they should be reexamined. Other potential adverse medication reactions include nausea, alopecia, menstrual disorder, amenorrhea, upper respiratory tract infection, UTIs, and leukemia. Mitoxantrone's role in the treatment of MS remains unclear due to the cardiac toxicity that limits its long-term use. More recent estimates also suggest the risk of leukemia may be as high as 1 in 145 patients, which has significantly decreased interest in its use for MS patients.[106]

Rituximab (Rituxan) and Ocrelizumab (Ocrevus)

Pharmacologically rituximab is a chimeric monoclonal antibody that targets the CD20 antigen on B cells. It is currently not FDA approved for the treatment of RRMS and PPMS, but is often used off-label for this indication. In one retrospective observational study, its use demonstrated decreased in annualized relapse rate in RRMS and PPMS patients, while the EDSS remained unchanged.[107] Therefore, patients with PPMS who are less than 51 years old and have at least one gadolinium-enhancing lesion may benefit from rituximab therapy when given an infusion twice yearly.[107] The most common adverse reactions seen in this study were mild infusion-related reactions.

Ocrelizumab is a humanized version of the rituximab monoclonal antibody, and theoretically, it has lower autoantibodies formation and infusion reactions than its chimeric counterpart. Its mechanism of action is unknown but is presumed to involve CD20 binding, a cell surface antigen present on pre-B and mature B lymphocytes. Blocking CD20 effectively suppresses immune responses through depletion of CD20-expressing B cells.[39] It is the first medication FDA approved for PPMS, and relapsing forms of MS.

Ocrelizumab has been associated with lower rates of disease activity and progression compared to interferon β_{1a} over the period of 96 weeks.[108] Its efficacy in PPMS patients was shown by approximately an 18% to 25% risk reduction in all study endpoints (ie, confirmed disability progression, timed 25-ft walk test [~7.5 m] performance, total volume of T2-weighted lesion, and decreased change in brain volume).[39]

Ocrelizumab's adverse events included infusion reactions necessitating subsequent dosing reductions, upper respiratory tract infections, and oral herpes activation. Neoplasms were also more common in the ocrelizumab group than placebo, with four patients receiving ocrelizumab developing breast cancer and three with basal cell carcinoma. Cervical adenocarcinoma in situ and basal cell carcinoma were the two neoplasms seen in the placebo group. This imbalance warrants ongoing evaluation in the context of the epidemiology of neoplasms in the MS population and the long-term experience with this and other CD20 treatments.[39] There have been a handful of cases with patients developing PML on ocrelizumab, but since all had natalizumab as prior therapy, they are considered carryover cases. In 2019, there was one case of a 78-year-old patient who developed PML on ocrelizumab and no prior DMT therapy, but other risk factors likely played a role in increasing this patient's risk. Regardless, monitoring for PML in all patients is recommended.

Ocrelizumab is given as a two-dose series via peripheral infusion, beginning with 300 mg given on day one and followed by another 300 mg on day 14. Subsequent doses of 600 mg are then given in 6-month intervals. Infusion rates are started at 30 mL/hr (for 300 mg in 250-mL bag starting doses) or 40 mL/hr (for 600 mg in 500-mL bag maintenance dose), which is stepped up based on patient tolerance, similar to rituximab. Monitor for infusion reactions throughout and up to 1 hour after infusion completion. The maximum infusion rate for the 300mg is 180 mL/hr and 200 mL/hr for the 600 mg dose. Before ocrelizumab treatment starts, patients should be screened for hepatitis B, and for active infections before each infusion.[109]

Remaining Questions for Disease-Modifying Therapy

⑨ Despite the results from well-conducted clinical trials, several relevant treatment issues remain including; (1) when to begin therapy, (2) which agent to initiate, and (3) when to switch and stop therapies. The AAN has developed evidence-based guidelines regarding DMT use in MS. Key recommendations regarding initiating, switching, and stopping DMTs are summarized in Table 74-3.[55,110]

Decisions about medication use for MS include determining the illness severity, medication efficacy and adverse medication effect risks, and costs related to the therapy. These medications slow the course of the illness but do not suppress it completely, and in some individuals, no apparent benefit is reported. The vast majority of untreated patients will have progressive disease over time, and even in acute lesions, there is significant axonal damage that is essentially irreversible. MRI data show that 80% to 90% of all new enhancing lesions are asymptomatic, suggesting that a "quiet" clinical course does not necessarily mean there is not an ongoing disease activity that ultimately will lead to cognitive deficits and progressive spastic paraparesis.

Very early therapy is effective. In patients with CIS and two or more T2 lesions on brain MRI (ie, at high risk for developing CDMS), placebo-controlled studies with all three of the IFN agents and glatiramer acetate have shown significant delay in a second attack and positive outcomes on a variety of MRI measures.[57,110] Currently, the FDA has approved IFN-β_{1b}, IFN-β_{1a} (Avonex), glatiramer acetate, and some of the newer DMTs for use in CIS patients with abnormal MRIs consistent with demyelination. The AAN and CMSC recommend that patients with relapsing disease should be initiated on an FDA-approved DMT as soon as possible following diagnosis.[55,56,110]

Which DMT to use in which patient is the second major issue as there has not been a single, randomized study comparing DMTs in similar patient populations at the same time.[112] In the case of the first-generation self-injectables (see Table 74-2), results from pivotal placebo-controlled trials were more similar than different, including a nearly identical one-third reduction in relapse rate for all four medications over two years. A small number of studies suggest that frequent administration of IFN at higher doses may be more efficacious than lower dose, less frequent administration.[113,114] Other studies argue against this,[111,115] and some note no outcome differences between standard and double dose IFN-β_{1b} and glatiramer acetate,[115,116] or between IFN-β_{1a} (Rebif) and glatiramer acetate.[117]

Further complicating this issue is our understanding of the clinical differences between IFN products and the development of neutralizing antibodies. Between 30% to 40% of patients receiving IFN-β_{1b} develop antibodies directed against the medication; however, the exacerbation rate in these patients was similar to that seen in placebo-treated patients.[118] Neutralizing antibodies can occur as early as three to six months into IFN-β_{1b} treatment and as late as 18 months, as this product is the most antigenic.[119] Additionally neutralizing antibodies were found in 22% of early trials with IFN-β_{1a} (Avonex), but later studies report an incidence of 2% to 5%. This difference may be due to a formulation change making the product less antigenic.[111,117] Percentages of antibody formation for Rebif (approximately 12%) are intermediate. They may occur in the first 9 to 15 months of treatment, similar to Avonex.[118,119] Approximately 6% of patients treated with natalizumab show neutralizing antibodies that seem to diminish efficacy.[74] The long-term clinical significance of these findings is not completely clear, although data confirms a negative relationship between neutralizing antibodies and relapses, MRI lesions, and disability progression.[119–122] It is unknown if these antibodies are cross-react between products, the duration of time in which they can be detected, and the impact corticosteroids have on their formation. Consensus guidelines outline when to test for neutralizing antibodies, which assay to use, or what titer cutoff to apply to patients in clinical settings exist.[123]

⑧ DMTs have been used to treat MS for more than two decades; however, patients continue to have more relapses, MRI lesions, disabilities, and ongoing disease progression to SPMS.[124] Although there is no accepted definition of treatment inadequacy, the Canadian Multiple Sclerosis Research Council has suggested a relatively simple approach that incorporates the elements of relapse rate, new MRI lesions, and change on the EDSS.[125] First, if significant and persistent IFN antibodies develop, switching to a non-IFN antibody (glatiramer acetate, natalizumab, ocrelizumab, fingolimod, siponimod, ozanimod, ponesimod, teriflunomide, dimethyl fumarate, diroximel fumarate, monomethyl fumarate, ofatumumab, mitoxantrone, or possibly rituximab[126]) is reasonable. A second option is the addition of an immunosuppressant, such as monthly methylprednisolone,[127] azathioprine, methotrexate, or mycophenolate. As noted earlier, natalizumab added to IFN-β_{1a} produces rare cases of PML, and should not be used clinically. Interestingly, the addition of a statin, specifically atorvastatin, into a beta-interferon agent may worsen MS,[128] although more research is needed.

Symptomatic Management

⑩ Many MS symptoms either do not require pharmacologic management or are nonresponsive. This section addresses the primary symptoms for which pharmacologic management may be beneficial (Table 74-4).[33,129–132]

Gait Difficulties and Spasticity

Gait problems can be caused by spasticity, weakness, ataxia, defective proprioception, or a combination of these factors. Spasticity is commonly encountered and tends to affect the legs more markedly than the arms, which can result in falls. As spasticity often presents late in the disease, the increased muscle tone of a spastic limb often lends pseudo-strength to patients with underlying weakness. While spasticity is amenable to pharmacologic intervention, muscle relaxants must not decrease muscle tone to the extent that ambulation is hindered.[33,130] Baclofen (Lioresal), a short-acting γ-aminobutyric acid (GABA) analog, is the preferred agent for spasticity and is started at 10 mg three times daily which is then titrated upward to achieve the desired response. Most patients respond with dosages between 40 and 80 mg/day, although some require dosages higher than the maximum recommended daily dose of 80 mg.[33,130] Due to oral baclofen's relatively short duration of action, continuous intrathecal administration of Gablofen may be used for patients unable to tolerate or unresponsive to oral therapy. Baclofen should not be abruptly discontinued to avoid seizures.[130]

Another effective agent for spasticity is tizanidine (Zanaflex), a short-acting, α-adrenergic agonist that acts in the CNS by increasing the presynaptic inhibition of motor neurons. Its efficacy is comparable to baclofen.[116] Starting at a dosage of 4mg at bedtime, slowly titrated up over two to four weeks based on clinical response. The effective dosages range from 2 to 36 mg/day. Sedation, dizziness, and dry mouth are commonly reported adverse effects, but hypotension, as well as rare but severe hepatotoxicity, can occur. Tizanidine can be added to baclofen in small dosages, sometimes resulting in smaller doses of each medication and better outcomes.

In patients unable to tolerate baclofen or tizanidine, diazepam (Valium; 2-10 mg/day), clonazepam (Klonopin; 1-3 mg/day), or dantrolene sodium (Dantrium; 100-400 mg/day) may be alternatives; however, they generally are less effective. Mild spasticity may respond to gabapentin (Neurontin; 1,800-3,600 mg/day) or tiagabine (Gabitril; 8-56 mg/day) may be useful but adverse medication reactions can prohibit their use. Pregabalin (Lyrica; 75-300 mg/day) has similar features as gabapentin but is approximately three times more potent and does not saturate the GI tract L-transporter system, so it may prove helpful in treating spasticity.

Botulinum toxin type A (Botox) is effective in alleviating spasticity.[33] The amount required to exert a pharmacological effect is often too excessive to use safely in the larger muscles; therefore, its use is best limited to smaller areas of focal muscle spasm.

An alternative approach for gait disruptions are K^+ channel blockers such as 4-aminopyridine (4-AP), which can potentiate synaptic transmission and increase muscle twitch tension. Similar to 4-AP, dalfampridine (Ampyra; 20 mg/day) can improve walking speed in patients with MS.[131,132,137,138] In other countries, dalfampridine is referred to as fampridine.[138] Common adverse medication reactions of dalfampridine include UTIs, insomnia, dizziness, headaches, and balance disorders. This agent is associated with the risk of seizures, particularly when the maximum dose of 10 mg twice daily is exceeded. It is contraindicated in patients with a seizure history, and a REMS program is used to manage these risks. It is essential to educate patients not to take products containing 4-AP with dalfampridine, as therapeutically, it is a comparable extended-release product, which also means the medication should not be chewed, crushed, or cut. If a dose is missed, patients should take it immediately, take their dose upon recognition and never double the dosage due to seizure risk.

Tremor

Cerebellar symptoms such as tremor can be troubling and difficult to control. Helpful medications include propranolol, primidone, and isoniazid.

Bowel and Bladder Symptoms

Incontinence, urgency, frequency, and nocturia, are indications of a hyperreflexic bladder (ie, inability to store urine) and are common complaints. A number of anticholinergic agents, including tricyclic antidepressants, are used to treat mild symptoms. Still, with all anticholinergic agents, great care must be used to avoid falls and decreased cognition. Antimuscarinic agents can also treat incontinence. In patients with significant sphincter detrusor dyssynergia, oral α-adrenergic blockers or intramuscular botulinum toxin type A may relax the internal sphincter (see Chapter 105, "Urinary Incontinence").

Intermittent self-catheterization and the Credé maneuver, with or without a concomitant anticholinergic agent, are recommended for large postvoid residual volumes (more than 100 mL) or when the urinary problem is hyporeflexic in nature (failure to empty). Cholinergic agents like bethanechol may also be used for a hyporeflexive bladder. Treatment is important as large post-void residual volumes increase UTI risk, and therefore, urinary acidifiers such as vitamin C or antiseptics such as methenamine mandelate may be used to prevent infections. Antibiotics used for UTI prophylaxis include sulfamethoxazole/trimethoprim, cephalexin, cinoxacin, and nitrofurantoin.

Constipation is the most common bowel complaint seen in patients with MS, as many medications (eg, opioids, anticholinergics) and voluntary water restriction in those patients with urinary urgency and incontinence may contribute to its risk. Increases in dietary fiber and hydration may alleviate this problem, but laxatives or enemas may be necessary (see Chapter 36, "Chronic Heart Failure").

Major Depression

Depressive symptoms and major depressive disorder are common in patients with MS. The risk of suicide may be increased markedly.[137] Patients should be monitored closely for symptomatology and treated accordingly (see Chapter 88 "Depressive Disorders"). IFN products and natalizumab should be used cautiously in patients with significant depressive symptoms.

Sensory Symptoms

Numbness and paresthesia are frequent sensory complaints related to MS, but usually do not require treatment. However, some patients may develop acute or chronic pain syndromes[130] such as trigeminal neuralgia and painful dysesthesias, for which treatment is necessary (see Chapter 79, "Pain Management").

Sexual Dysfunction

Sexual dysfunction in both men and females is common and counseling should be offered to both partners. Phosphodiesterase inhibitors or Alprostadil, a prostaglandin E1, can be very effective for erectile dysfunction (see Chapter 103, "Erectile Dysfunction"). Sildenafil (Viagra) is currently being studied in females with MS and sexual dysfunction. Bupropion (Wellbutrin) is the preferable antidepressant in patients for whom sexual dysfunction is a concern, due to its lower incidence of sexual adverse medication reactions.

Fatigue

Fatigue a common complaint in MS patients, can be severely disabling, but often overlooked. Typically, it presents in the mid-to-late afternoon and can increase with heat exposure, exertion, concurrent infection, spasticity, weakness, and depression. Amantadine hydrochloride (100 mg twice daily) may offer significant relief.[33,129] Methylphenidate (Ritalin), dextroamphetamine (Dexedrine, Adderall), and related products are used commonly. Modafinil (Provigil), 200 to 400 mg daily may be helpful for MS-related fatigue. Its *R*-enantiomer, armodafinil (Nuvigil), is dosed at 150mg or 250 mg daily, reaches peak concentrations more quickly and has potentially fewer adverse medication reactions than modafinil. In patients suffering from both depressive symptoms and fatigue, a more activating antidepressant such as fluoxetine may be employed.

Cognition

Cognitive dysfunction affects up to 50% or more of patients and manifests itself as word-finding difficulties and problems with concentration and short-term memory. Carefully review the patient's current medications before adding pharmacotherapy for cognitive dysfunction, as there are reports that statins and long-term proton-pump inhibitors can cause memory concerns. Cognitive dysfunction can be treated with stimulants or cholinesterase inhibitors if appropriate.

Pseudobulbar Palsy

Pseudobulbar palsy is a condition caused by progressive degeneration of the corticobulbar tract in patients with MS. Symptoms include dysarthria, dysphonia, dysphagia, and sudden, inappropriate, uncontrollable, emotional outbursts such as crying or laughing. A combination product of dextromethorphan and quinidine 20 mg/10 mg (Nuedexta) is used for its treatment, however, its mechanism of action is unknown. It is dosed as one capsule daily for one week, followed by one capsule twice daily. The quinidine included in this product inhibits the CYP2D6 enzyme leading to an increased dextromethorphan serum concentrations.

Complementary and Alternative Therapies for MS

Approximately 33% to 80% of patients with MS use complementary and alternative medicine (CAM) therapies.[133] These include the use of diet and dietary supplements such as vitamins, minerals, and herbs. Antioxidant supplements vitamin A, C, E, α-lipoic acid, coenzyme Q10, grape seed, pine bark extracts, mangosteen, and acai have suggestive benefits. However, for patients with MS, the antioxidant supplements hold a theoretical risk given their ability to stimulate the immune system (T cells and macrophages). Thus, their use may worsen or exacerbate their disease by counteracting the effects of immunomodulators. Other immune-stimulating supplements such as garlic, ginseng (Asian and Siberian), Echinacea, cat's claw, astragalus, alfalfa, and stinging nettle should be used with caution.[134]

Table 74-5 outlines updated AAN evidence-based CAM recommendations in MS.[133] The safety of these therapies when used in combination with DMTs, has not been studied. Nor has information about medication interactions, however, healthcare providers can provide objective information regarding CAM use in MS and can assist their patients in making decisions.[122] A few of the CAM therapies listed below have been given Level A recommendations, meaning their use has been established but for most a Level B recommendation has been given, meaning they are probably effective.[122]

Vaccine Recommendations

Avoid live vaccine administration in any patients with MS receiving DMTs due to immunosuppression and the potential for the live virus vaccines to increase MS disease activity. Vaccines considered safe include the human papillomavirus, tetanus, rabies, and inactivated polio.[56] A yearly flu shot is recommended for all patients with MS, including those receiving any DMTs, while the intranasal influenza vaccine FluMist, a live-attenuated vaccine, is not. It is unknown if the intranasal influenza vaccine directly interacts with DMTs.[132] An exception to this rule applies to patients taking fingolimod, and alemtuzumab, who are negative for varicella-zoster antibodies. They should receive the non-live virus immunization at least 2 months before beginning treatment to allow time to mount an antibody response prior to immunosuppression. For unvaccinated patients at high risk for hepatitis B exposure, this vaccine should be given prior to ocrelizumab doses. This vaccine is not necessary for patients at low risk for exposure.[56]

EVALUATION OF THERAPEUTIC OUTCOMES

For those with acute MS exacerbations, treatment response is commonly seen within days. However, the clinician and patient should recognize that short-term (days to weeks), little or no apparent benefit may be noted when using a DMT. Therefore, therapeutic outcome evaluation is conducted over months to years by monitoring MS exacerbations, hospitalizations, disease progression, and disability measured using scales such as EDSS. Patients should be given realistic goals and treatment expectations to maximize medication adherence, in addition to being fully counseled regarding adverse effects. They should also be encouraged to participate in the evaluation of therapeutic response and actively encouraged to adhere to their prescribed regimens. If nonadherence is suspected, an investigation into barriers, such as injection fatigue or intolerable adverse medication reactions, should be done. Discussion around medication cost and/or switching agents to one that may provide increased adherence should also be done.

Each DMTs has specific safety monitoring recommendations to follow. Specific safety monitoring parameters for the newer DMTs can be found in Table 74-2. In general, patients on any DMT should receive regular laboratory monitoring and close observation, including regular neurologic examinations, frequent evaluation for adverse effects, and/or changes in disability. Natalizumab and alemtuzumab have REMS programs, and fingolimod, siponimod, ozanimod, ponesimod, and cladribine have Medication Guides to monitor safety. Healthcare providers should follow the requirements of these programs. Laboratory monitoring for IFN therapy should include a CBC, platelet count, and LFTs completed at baseline, every 3 months for one year, and every 6 months after that. However, glatiramer acetate requires no specific laboratory monitoring. Teriflunomide requires a transaminase, bilirubin, CBC, tuberculin skin test, and blood pressure before therapy is started. Additionally, alanine aminotransferase should be monitored every 6 months after starting treatment. Patients on teriflunomide should be evaluated for renal failure and increased serum potassium as needed. Dimethyl fumarate requires a CBC prior to beginning therapy, within 6 months after treatment initiation, followed by annually. During these times, LFTs should also be monitored for patients on dimethyl fumarate.

CONCLUSION

The diagnosis and treatment of MS can be difficult, and until recently, treatment was particular to the MS center or treating neurologist. The AAN has the most updated guidelines for DMTs for adults with multiple sclerosis.[55] These focus on shared patient-centered decision making, where the patient is given general information about dosing schedule, route of administration, and adverse medication reactions for their specific disease presentation. The team works with the patient to make treatment decisions on how to best help the patient manage their illness, working to improve primary, secondary, and tertiary disease outcomes. More aggressive treatment with alemtuzumab, fingolimod, or natalizumab is required for people with highly active MS, and with ocrelizumab for patients with PPMS where the benefits outweigh the risks.[55] The most severe adverse effect associated with MS treatments is PML, and guidelines for natalizumab, fingolimod, rituximab, ocrelizumab, and dimethyl fumarate specifically note that patients should be counseled on this adverse effect. By moving to a patient-centered MS care approach, disease outcomes (due to increased adherence) and treatment satisfaction should improve as it is only through collaboration as a care team that we will be able to combat this debilitating disease.

ABBREVIATIONS

AAN	American Academy of Neurology
ACTH	adrenocorticotropic hormone
ADCC	antibody-dependent cell-mediated cytolysis
4-AP	4-aminopyridine
BCRP	breast cancer-resistant protein
CAM	complementary and alternative medicine
CBC	complete blood count
CDMS	clinically definite multiple sclerosis
CIS	clinically isolated syndrome
CNS	central nervous system
CSF	cerebrospinal fluid
DMT	disease-modifying therapy
EBNA	Epstein-Barr nuclear antigen
EBV	Epstein-Barr virus
ECG	electrocardiogram
EDSS	expanded disability status scale
GI	gastrointestinal

HLA	human leukocyte antigen
IAR	infusion-associated reaction
IFN	interferon
IgG	immunoglobulin G
IL	interleukin
INR	international normalized ratio
IRIS	immune reconstitution inflammatory syndrome
ITP	immune thrombocytopenia
IV	intravenous
JCV	John Cunningham virus
LFT	liver function test
MBP	myelin basic protein
MHC	major histocompatibility complex
MRI	magnetic resonance imaging
MS	multiple sclerosis
MSFC	multiple sclerosis functional composite
PEG	polyethylene glycol
PLEX	plasma exchange
PML	progressive multifocal leukoencephalopathy
PPMS	primary-progressive multiple sclerosis
PRMS	progressive-relapsing multiple sclerosis
REMS	Risk Evaluation and Mitigation Strategy
RRMS	relapsing-remitting multiple sclerosis
SPMS	secondary-progressive multiple sclerosis
TGF	transforming growth factor
Th	T-helper cells

THC	tetrahydrocannabinol
Treg	T-regulatory cells
UTI	urinary tract infection
VCA	vascular cell adhesion
VCAM	vascular cell adhesion molecule
VEP	visual-evoked potential
VLA-1	very-late antigen 1

SELF-ASSESSMENT QUESTIONS

1. At the time of diagnosis, which of the following forms of multiple sclerosis (MS) is the *most* common?

   A. Primary-progressive

   B. Relapsing-progressive

   C. Relapsing-remitting

   D. Secondary-progressive

2. When initiating natalizumab therapy 300 mg IV every four weeks, which of the following is *not* a monitoring parameter?

   A. Liver function tests

   B. Anti-JCV antibodies

   C. Tuberculin skin test

   D. MRI

3. Which of the following is used in the treatment of an exacerbation (attack/relapse) of MS?

   A. Oral immunoglobulin

   B. High-dose IV methylprednisolone

   C. Low-dose oral prednisone

   D. Dalfampridine

4. PJ is a 47-year-old female with RRMS who presents to the clinic with complaints of fatigue. The physician decides to prescribe a medication for the symptomatic treatment of fatigue. Which of the following agents would *not* be appropriate?

   A. Methylphenidate 5 mg every morning

   B. Modafinil 200 mg every morning

   C. Amantadine 100 mg twice daily

   D. Dextromethorphan/quinidine 20 mg / 10 mg every morning

5. Which is *true* about spasticity in MS?

   A. Spasticity occurs early after a patient is diagnosed with MS

   B. Increased muscle tone due to spasticity in late-stage MS can help to decrease falls due to weakness

C. Fluoxetine is a first-line agent to treat spasticity

D. Baclofen is useful orally, intrathecally, and IV for spasticity

6. When counseling a patient about interferon therapy for MS, you should communicate to the patient which important aspect regarding efficacy?

A. They will start to notice a change in symptoms immediately.

B. They must freeze the medication.

C. It may take up to one or two years to see a change on the MRI.

D. The medication works best if a double dose is given.

7. Interferon-β_{la} (Rebif) differs from Interferon-β_{la} (Avonex) in what way?

A. Rebif is given once per week.

B. Rebif is given as an intramuscular injection.

C. Rebif is given three times per week.

D. Rebif causes tissue necrosis.

8. SW is a 72-year-old male currently on Interferon-β_{la} (Rebif) 44 mcg subcutaneously three times per week, warfarin, and amiodarone. In the past six months, he has had three exacerbations and multiple new enhancing lesions on MRI. Following the discontinuation of Rebif what is the best next step in his course of therapy?

A. Natalizumab

B. Glatiramer acetate

C. Mitoxantrone

D. Fingolimod

9. Which of the following is *not* a side effect seen with Sphingosine-1 phosphate receptor modulators (fingolimod, siponimod, ozanimod, ponesimod)?

A. Bradycardia

B. Depression

C. Infection

D. Increased Liver Enzymes

10. SC, a 30-year-old female, was prescribed teriflunomide 7 mg orally daily for the treatment of her relapsing MS. Which of the following counseling points is *false*?

A. Teriflunomide is a pregnancy category X medication and a contraceptive method is recommended.

B. Alopecia, nausea, headache, and paresthesias are common side effects associated with teriflunomide.

C. A cholestyramine washout may be considered if pregnancy is desired.

D. Teriflunomide causes secondary leukemia in 1 in 1,400 patients.

11. Efficacy of the ocrelizumab can be attributed to which mechanism of action?

    A. Depletion of CD20 expressed B-cells

    B. α_1- and β_1-blockade

    C. Sphingosine-1-phosphate receptor modulation

    D. Blockade of t-lymphocyte migration into CNS

12. Diroximel fumarate (Vumerity) is thought to act by which of the following mechanisms of action?

    A. Decrease matrix metalloproteinases

    B. Inhibition of the proliferation of reactive T cells

    C. Decreased number of adhesion molecules

    D. Activation of Nrf2 pathway

13. MB, a 35-year-old female with RRMS, asks you about an MS drug that requires a 6-hour observation period. Which of the following drugs requires a 6-hour observation monitoring period?

    A. Ocrelizumab

    B. Natalizumab

    C. Fingolimod

    D. Ponesimod

14. CC, a 52-year-old female, is having difficulty walking without stopping every 25 ft (~7.5 m) or so to take a break. Which of the following drugs is the most appropriate choice for CC at this time?

    A. Ozanimod

    B. Modafinil

    C. Interferon-β_{la} (Extavia)

    D. Dalfampridine

15. Which agent is contraindicated in pregnancy?

    A. Siponimod

    B. Teriflunomide

    C. Monomethyl fumarate

    D. Natalizumab

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** RRMS is the most common form of diagnosed MS, which accounts for about 85% of patients.

2. **C.** A tuberculin skin test is only indicated with the use of teriflunomide and alemtuzumab (Table 74-5).

3. **B.** High-dose methylprednisolone is used first-line to treat acute relapses/exacerbations.
4. **D.** Dextromethorphan/quinidine 20 mg / 10 mg is used to treat pseudobulbar affect, not fatigue.
5. **B.** Increased muscle tone lends to pseudo-strength with underlying weakness. Spasticity usually occurs late in the disease process. Fluoxetine is best used for fatigue if a patient is also depressed due to its activating mechanism. Baclofen is not used IV, only oral and intrathecally.
6. **C.** Immediate changes in symptoms are not noted with interferon therapy, and it can take up to 1 to 2 years to see a change on MRI. Never double the dose of the medication, and the medication should not be frozen.
7. **C.** Avonex is given IM one time weekly, while Rebif is given by subcutaneous injection three times weekly. Their side effect profiles are similar but may be less frequent with Avonex due to less frequent injections (Table 74-3).
8. **A.** Natalizumab is the most effective DMT available, and due to the patient having multiple relapses/exacerbations, multiple new MRI lesions, and his older age, it is best to give a more aggressive treatment since the disease is progressing quickly. Fingolimod is not as effective as natalizumab, and the patient is on amiodarone, which is contraindicated with fingolimod therapy due to bradycardia and heart block. Glatiramer acetate would give no increased benefit compared to interferon therapy in the patient.
9. **C.** Depression is a side effect for interferon therapies and not S1P receptor modulators (Table 74-5).
10. **D.** Teriflunomide use is not associated with secondary leukemia, but mitoxantrone is associated with this adverse effect.
11. **D.** The mechanism of action of ocrelizumab causes antibody-dependent cytotoxicity through selectively binding B-cells with CD20.
12. **D.** Although the exact mechanism of action of diroximel fumarate is unknown, it is thought to be due to anti-inflammatory and cytoprotective properties via activation of the Nrf2 pathway.
13. **C.** Fingolimod has a 6-hour first-dose observation period due to risk of bradycardia. Siponimod and ozanimod carry a warning and only require the 6-hour observation period for patients with high risk for bradycardia. Ponesimod only requires a 4-hour observation for certain patient populations.
14. **D.** Dalfampridine is specifically used to increase walking speed.
15. **B.** Teriflunomide is contraindicated in pregnancy, and an accelerated elimination procedure is put in place to clear the drug if needed for contraception for both females and males.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 75: Epilepsy

Viet-Huong V. Nguyen; Sunita Dergalust; Edward Chang

KEY CONCEPTS

KEY CONCEPTS

① The goal of pharmacotherapy is seizure freedom with minimal adverse effects. Between 60% and 80% of patients can achieve this.

② Accurate classification and diagnosis of seizure type/epilepsy syndrome, including where seizures begin, is critical to selection of appropriate pharmacotherapy.

③ Besides seizure type, antiseizure medication (ASM) selection depends on patient characteristics such as age, sex, ethnicity, susceptibility to adverse medication effects, comorbid conditions, ability to adhere with the prescribed regimen, presence or absence of insurance coverage, and need for therapeutic levels to be reached quickly.

④ Pharmacotherapy for epilepsy is highly individualized and requires dose titration to optimize therapy (maximal seizure control with minimal or no adverse medication effects).

⑤ If the therapeutic goal is not achieved with monotherapy, a second ASM, preferably with a different mechanism of action, can be added. The patient's ASM can also be switched to an alternative single agent.

⑥ Patients who do not respond to pharmacotherapy should be referred to a comprehensive epilepsy center to determine if nonpharmacologic treatments such as surgery are potential options.

⑦ In general, first-generation ASMs are very efficacious but have complex pharmacokinetics, multiple medication interactions, and an increased incidence of adverse effects, which make them more complicated to manage than either the second- or third-generation ASMs.

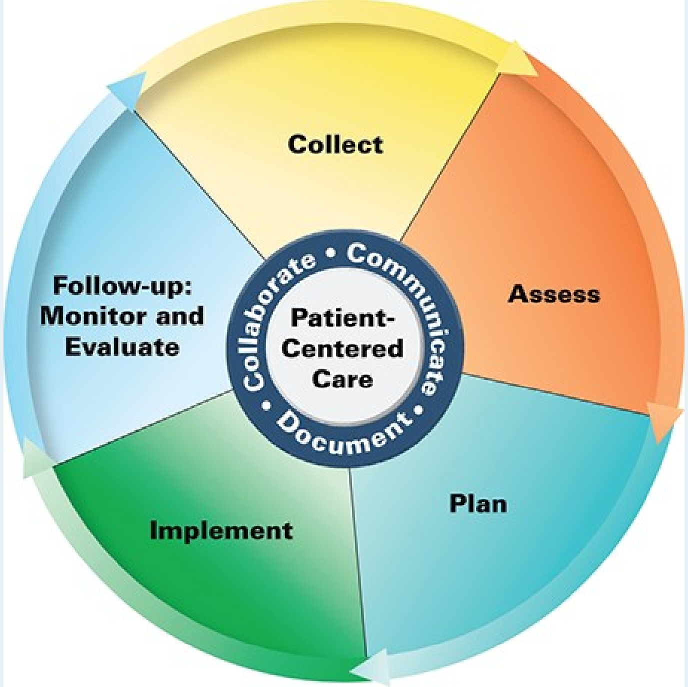
⑧ Second-generation ASMs have unique mechanisms of action and are as efficacious as first- and third-generation ASMs with better tolerability. They are generally considered first-line epilepsy pharmacotherapy.

⑨ Third-generation ASMs should be reserved for failure of other agents due to cost and limited long-term experience.

⑩ 20% to 35% of patients will have unsatisfactory control with ASMs and will be considered to be treatment-resistant.

PATIENT CARE PROCESS

Patient Care Process for Epilepsy



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient-specific demographics (eg, age, race, sex, pregnancy status, and desire for pregnancy)
- A detailed description of seizure semiology from the patient and a witness of the seizure, including the following:
    - Degree of mental status impairment during the event
    - Presence of ictal motor, sensory, autonomic, or other features at onset of the seizure (Fig. 75-1)
    - Tongue biting, cheek biting, and bladder or bowel incontinence during the seizures
    - Seizure time course and any postictal phenomena (eg, fatigue, headaches, confusion, and psychosis)
- Frequency of seizure events and any precipitating factors
- Information on comorbid medical psychiatric, and neurodevelopmental conditions including depression, anxiety, and learning and development conditions
- Family history of epilepsy, risk factors for epilepsy including injury at birth, history of meningitis or encephalitis, history of traumatic brain injury
- Current and past medications including antiseizure medications (ASMs)
- Duration of past ASM therapy and response to each ASM (eg, decrease or increase in seizure frequency and adverse medication reactions experienced)
- Allergies to medications including ASMs
- Laboratory values for electrolytes and glucose to rule out provoked seizures, baseline test for renal function, liver function, and complete blood count (CBC)
- Magnetic resonance imaging (MRI) of brain without contrast

- Electroencephalogram (EEG)

Assess

- Seizure, epilepsy, and epilepsy syndrome classification (Figs. 73-1 and 73-2)
- Duration of therapy on current ASM regimen
- Seizure freedom on current ASMs or current seizure frequency if not seizure-free (Fig. 75-3)
- Adverse medication reactions experienced on current ASMs (Fig. 75-3)
- Factors for optimal ASM selection including patient-specific factors (Table 75-1)
- Other quality-of-life factors

Plan*

- Determine need for monotherapy (usually at initiation of therapy) or polytherapy (usually after failure of first or second ASM) (Fig. 75-3)
- Select an ASM that has efficacy for the specific seizure type, epilepsy, or epilepsy syndrome (Table 75-1)
- Considering patient-specific factors, select an ASM with:
  - Most tolerable adverse medication reaction profile (Table 75-1)
  - Least incidence of interactions with other medications (Tables 75-3 and 75-5)
  - Least complicated ASM pharmacokinetics (Table 75-4)
  - Utility in treating the patients' other comorbid conditions (Table 75-2)
- Create a patient-specific monitoring plan based on the therapy chosen

Implement*

- Identify initial dose and maintenance dose (Table 75-4) along with appropriate formulation (Table 75-2) and dosage size (eg, 25 mg tablets, 100 mg capsules, 250 mg/5 mL oral solution, 1,500 mg/100 mL of diluted solution for intravenous injection) to meet the patients' needs
- Counsel patient on dose, dose formulation, and how to titrate appropriately
- Provide patient with seizure and adverse medication reaction diary and counsel patient and family on how to record in the diary
- Ensure completion of prior authorizations for insurance coverage as needed
- Ensure prescription is provided on appropriate controlled substance prescription form as needed for any scheduled preparations (Table 75-2)

Follow-up: Monitor and Evaluate

- Treatment response including increase or decrease in seizure frequency and changes in seizure semiology
- Laboratory assessments including CBC, chemistries, liver function tests, and ASM serum concentrations if needed
- Monitor for common dose-related, rare idiosyncratic, and long-term adverse medication reactions
- Monitor for other comorbid conditions such as depression, anxiety, suicidal ideation, and social adjustment
- Monitor for learning and development issues in children

- Monitor seizure triggers
- Monitor adherence

Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Use the following webpage (*Epipick tool)* to help identify the possible epilepsy types. This resource will also help you select appropriate medications for your patient based on patient-specific characteristics and comorbidities.

Use the following link (*https://https://www.ilae.org/*) to get acquainted with the International League Against Epilepsy (ILAE), a world association of health professionals and scientists working together to understand, diagnose, and treat patients with epilepsy. Of particular interest may be the section on education which provides links to infographics and videos as well as the section on guidelines, which provides current practice guidelines, reports, and position papers.

INTRODUCTION

Epilepsy is a common neurologic condition in which a person is prone to recurrent epileptic seizures. There are many types of epilepsies characterized by different seizure types, ranging in severity and etiologies. While the specific pathophysiologic mechanisms behind different epilepsies are complex, the general pathophysiologic process underlying all epilepsies is disturbed regulation of electrical activity in the brain resulting in synchronized and excessive neuronal discharge.

Beyond seizures, people with epilepsy face many challenges, including increased risk of neurodevelopmental delay, cognitive impairment, comorbid depression and anxiety. Furthermore, patients with epilepsy may face educational and vocational challenges, have difficulties with independent living, and be victims of stigma and common public misunderstanding. The International League Against Epilepsy (ILAE) defines epilepsy not only as "a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures" but also by "the neurobiologic, cognitive, psychological, and social consequences of this condition."[1] Clinicians treating epilepsy must address these common psychosocial issues and comorbidities. Pharmacotherapy should be selected to not only reduce the frequency of seizures as much as possible, but also to minimize adverse medication reactions, address coexisting health and social conditions, and enhance overall quality-of-life (QOL) for patients.

EPIDEMIOLOGY

Epilepsy is the fourth most common neurologic disorder globally and in the United States; only following stroke, migraine, and Alzheimer disease. In the United States, approximately 3.4 million people suffer from epilepsy with a prevalence of 1.2%. While epilepsy is a chronic disease that can present at all ages, the highest number of new epilepsy cases (incidence) will occur in childhood and the older adult population. Among children, epilepsy has the highest incidence in children under 5 years of age with most new cases occurring under 2 years of age. In older populations, the high frequency of epilepsy is now garnering attention as 1.5% of people older than 65 are affected by epilepsy in the United States.[2,3]

The majority of patients with epilepsy has a good prognosis and will be able to attain seizure freedom. However the mortality rate of patients with epilepsy is two to three times that of the general population and life expectancy may be reduced.[4] Increased mortality has been attributed to a wide variety of causes including sudden unexplained death in epilepsy (SUDEP).[5] While the exact mechanisms underlying SUDEP are unclear, recent research suggests there may be a cardio-respiratory mechanism involved.[5] Although it is rare in patients with well-controlled epilepsy, SUDEP accounts for up to 15% of all epilepsy-related deaths, with a lifetime risk of 4.6% to 8%.[5]

All individuals with epilepsy experience seizures; however, not all individuals who experience seizures will be diagnosed with epilepsy. Some seizures are provoked and occur as a result of systemic, toxic, or metabolic insults such as substance use; alcohol, barbiturate, or benzodiazepine withdrawal; or acute neurologic (eg, brain hemorrhage) or systemic illnesses (eg, hypocalcemia, hypoglycemia, uremia, and eclampsia). Furthermore, some patients will have seizures only associated with fever (eg, febrile seizures). In all of these situations, seizure occurrence does not generally constitute epilepsy, but rather are a symptom of the provoking insult. Once the provoking insult is removed or treated, there is not "an enduring predisposition to generate epileptic seizures." Each year, 120 per 100,000 people in the United States will be evaluated for a newly recognized seizure (provoked or unprovoked), but only 40 to 70 cases per 100,000 will be diagnosed with epilepsy. At least 10% of the general population will have at least one seizure from *any* cause in their lifetime.[2,3]

ETIOLOGY

Thousands of medical conditions can cause epilepsy, ranging from genetic predisposition to acquired injury (eg, stroke or traumatic brain injury). The most common causes vary depending on the population of interest. For instance, childhood-onset epilepsy is predominantly caused by genetic and/or developmental structural abnormalities, while epilepsy with an onset at older age is most often caused by acquired structural injury (eg, stroke or traumatic brain injury). Therefore, epilepsy etiologies can be generally classified into six categories reviewed here: (1) genetic; (2) structural; (3) infectious; (4) metabolic; (5) immune; and (6) unknown.[6] It is important to note that these categories are not mutually exclusive.

Genetic Etiology

Epilepsies with genetic etiology usually present in infancy or childhood with examples being (1) Dravet syndrome associated with mutations in sodium channel, voltage-gated, type I alpha subunit (SCN1A), (2) childhood absence epilepsy (CAE) associated with many different mutations in T-type Ca^{2+} channels and GABA-receptor subunits, and (3) Juvenile Myoclonic Epilepsy (JME) associated with many different mutations including those in the EF-hand containing protein-1 (EFHC1) and intestinal cell kinase (ICK).[7–11] Prior to 2010, genetic epilepsies were labeled as primary generalized epilepsy or idiopathic generalized epilepsy (IGE), as no clear structural brain abnormalities were found to be responsible for the epilepsy.[6] However, as most of these disorders have abnormalities at the molecular level they are now also called genetic generalized epilepsies.[6] Genetic etiologies usually pass from generation to generation but can also arise from sporadic mutations, and cannot be acquired after birth.

Structural Etiology

Structural etiologies refer to abnormalities visible on structural neuroimaging, and are either acquired or of genetic origin.[6] Common epilepsies caused by structural abnormalities include cortical dysplasia, mesial temporal lobe epilepsy, and posttraumatic epilepsy. In general, cortical dysplasia is a common cause of childhood onset medication-resistant epilepsy and is a result of disruptions in neuronal migration, proliferation, and differentiation during brain development, leading to disorganization of the normal structure of the cerebral cortex in certain brain areas. In general, mesial temporal lobe epilepsy is a common type of adult-onset epilepsy responsible for many of the medication-resistant epilepsies seen in tertiary care epilepsy clinics. In this structural form of epilepsy, sclerosis occurs in the hippocampus, the main structure of the mesial temporal lobe, and is characterized by glial scarring, reduced hippocampal volume as seen on magnetic resonance imaging (MRI), and decreased cellular density as seen on biopsy.[12] In contrast, traumatic brain injury epilepsy results from blunt force injury or stroke that causes structural lesions in the brain.[6]

Infectious Etiology

Infections are the most common epilepsy etiology worldwide[6] and typically occurs when a patient develops epilepsy as the sequelae of an infection, not when a patient experiences seizures in the setting of acute infection such as meningitis or encephalitis. In developing countries, the most common acquired infectious epilepsy is from neurocysticercosis, a parasitic infection of the brain that results from ingestion of pork tapeworm eggs, causing subsequent structural injury that promotes the development of epilepsy.[6]

Metabolic, Immune, and Unknown Etiology

Both the metabolic and immune etiologies of epilepsy are less common, although they are increasingly being recognized and understood.[6] An interesting metabolic etiology is Lafora disease, which is associated with abnormal glycogen metabolism and subsequent development of insoluble glycogen inclusion bodies resulting in epilepsy.[13] Immune epilepsies include anti-*N*-methyl-D-aspartate (anti-NMDA) receptor encephalitis which causes autoimmune-mediated central nervous system (CNS) inflammation and resulting epilepsy.[6] While both of these etiologies carry specific treatment implications, treatment implications are evolving. Patients can also present with unprovoked seizures that do not have an identifiable cause, and thus by definition have epilepsy of unknown cause.[6] While standard epilepsy workup procedures need to be followed, it is possible that these epilepsies may be due to an as-yet-unidentified gene or may be the consequence of an as-yet-unrecognized-structural or metabolic disorder.

Risk Factors and Seizure Triggers

While certain risk factors may suggest a predisposition to epilepsy, they are not necessarily causative, as known epilepsy risk factors include premature birth with small gestational weight, perinatal injury (eg, anoxia), history of alcohol withdrawal seizures, history of febrile seizures, and family history of seizures.[14] While the presence of such risk factors aid in establishing the diagnosis of epilepsy and may help in identifying the underlying epilepsy etiology, they may not explain the mechanistic cause of seizures.

Many factors trigger seizures in susceptible individuals, with two of the best known seizure triggers being hyperventilation and photostimulation (eg, flashing lights or rapidly changing or alternating images) in certain genetic epilepsies including juvenile myoclonic epilepsy and childhood absence epilepsy. Additional triggers include physical and emotional stress, sleep deprivation, sensory stimuli, and hormonal changes occurring around the time of menses, puberty, or pregnancy, as all of these have been associated with the onset of or an increased frequency of seizures. Lastly, medications such as theophylline, high-dose phenothiazines, antidepressants (especially bupropion), alcohol and substance use have all been associated with lowering seizure threshold and provoking seizures in patients with epilepsy.[15]

PATHOPHYSIOLOGY

The underlying general pathophysiologic process for all epilepsies is neuronal hyperexcitability and hypersynchronization. Initially during a seizure, a small number of hyperexcitable neurons fire abnormally in synchrony resulting in breakdown of normal membrane conductances and inhibitory synaptic currents. This allows the excess excitability to spread, either locally to produce a focal seizure, or the seizure is propagated by physiologic pathways and networks to involve more remote areas, or more widely to produce a generalized seizure.[16]

In general, neuronal hyperexcitability occurs because there is an enhanced predisposition of a neuron to depolarize and discharge when stimulated. While this may occur as the result of multiple mechanisms, alterations in the number, type, and biophysical properties of voltage- or ligand-gated K^+, Na^+, Ca^{2+}, and Cl^- ion channels in neuronal membranes are thought to play a significant role.[17] In fact, many of the available antiseizure medications (ASMs) have mechanisms of actions that act on these specific ion channels, highlighting the importance of these channels in promoting hyperexcitability. Carbamazepine and phenytoin reduce neuronal excitability by binding sodium channels in their inactive state and slowing channel recovery from inactivation, thereby preventing hyperexcitable neurons from rapidly and repetitively firing; this also blocks firing in a use-dependent fashion.[18,19] Benzodiazepines, in contrast, bind to the gamma subunit of the $GABA_A$ receptor leading to an increase in chloride ion conductance and inhibition of action potentials.[20] Mutations within these ion channels have been associated with multiple different epilepsies.[11] While the exact nature of these alterations have not been fully elucidated, these genetic alterations may result in differences between the various genetic epilepsies.

Other mechanisms of epileptogenesis, which may play roles in hyperexcitability, are related to alterations in vesicle trafficking and neurotransmitter release. For instance, synaptic vesicle protein 2A ($SV2_A$), a protein responsible for the fusion of vesicles to the membrane, is upregulated in certain models of epilepsy, and is the target of the second- and third-generation ASMs, levetiracetam and brivaracetam, respectively.[21] Alterations in neurotransmitter uptake and metabolism may also play a role in the pathogenesis of epilepsy.[22] An example of this comes from vigabatrin, which is an irreversible inhibitor of γ-aminobutyric acid transaminase (GABA-T).[23] As this enzyme is responsible for the metabolism of the inhibitory neurotransmitter GABA, this medication is thought to increase GABA through GABA-T inhibition.[23]

Additionally, there are many other possible hyperexcitability promoting mechanisms that may be important in the pathophysiology of epilepsy, including possible biochemical modifications of receptors, modulation of second messaging systems and gene expression, and changes in extracellular ion concentrations.[22] Hyperexcitability that results in increased firing of random individual neurons does not result in epileptic seizures, as synchronization of excessive neuronal firing is required.[24] The intrinsic organization of local circuits of certain cerebral structures including the hippocampus, the neocortex, and the thalamus contributes to synchronization and promotes generation of epileptiform activity. That is why many epileptic networks originate in these specific brain regions.[24,25] Modifications in the ratio and function of inhibitory circuits in these structures play an important role in promoting epileptogenesis, as a large number of these neurons are interconnected and can become simultaneously inhibited, and then synchronously excited. Although under normal circumstances, these neurons are asynchronous, it is believed that under abnormal circumstances, they become synchronous and act as pacemakers promoting epileptiform activity. Sprouting and reorganization of neuronal projections in abnormal tissue or after neuronal injury (eg, head trauma or stroke) may also lead to increased connectivity between neurons and a chronic susceptibility to seizures.[24] Therefore, both excitation and inhibitory connections lie at the heart of the pathophysiologic mechanisms behind epileptogenicity.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Epilepsy

Focal Aware Seizures

- Patients retain awareness of themselves and their environment including external stimuli.

Focal Impaired Awareness Seizure

- Patient has impaired awareness at any time during the seizure
- May be able to respond to questions during the seizure, but inappropriate response
- May not recall actions after event

Motor signs

- Automatisms: automatic behaviors like lip smacking, chewing, picking at clothing
- Atonic: loss of tone, going limp
- Clonic: rhythmic jerking or twitching of arm, shoulder, face, or leg
- Spasm: trunk flexion
- Hyperkinetic: thrashing/pedaling
- Myoclonic: arrhythmic jerking of arm, shoulder, face, or leg
- Tonic: extension or flexion postures

Nonmotor signs

- Autonomic: flushing, sweating, piloerection, salivation, pallor
- Behavior arrest: pausing, freezing, activity arrest
- Cognitive: language problems, thinking problems, memory phenomenon, and feelings of familiarity (déjà vu) or unfamiliarity (jamais vu)
- Emotion: feelings of fear, depression, joy, anger, extreme aberration of behavior
- Sensory: numbness, tingling, sounds (ringing/buzzing), smells, tastes, visions (hallucinations), vertigo

Focal to Bilateral Tonic–Clonic

- Focal seizure with impaired awareness which progresses to bilateral convulsive features such as with tonic–clonic motor features

Generalized Onset

- Impaired awareness

Motor signs (more common symptoms described below only)

- Tonic–clonic: sudden sharp tonic stiffening of muscles with a subsequent period of clonic movements such as rhythmic jerking of arms and legs (previously called "grand mal")
- Clonic: rhythmic jerking or twitching of arm, shoulder, face, or leg
- Myoclonic: arrhythmic jerking of arm, shoulder, face, or leg
- Atonic: loss of tone, going limp
- Epileptic spasms: trunk flexion

Nonmotor/absence (more common symptoms described below only)

- Typical: sudden arrest of behavior, blank stare with brief upward rotation of the eyes lasting 2 to 30 seconds
- Eyelid myoclonia: lid jerks

An epileptic seizure is defined as a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.[3] They can manifest physically in a variety of ways and can range from intense involuntary repetitive muscular contractions (eg, convulsions) to subtle alterations in sensation or consciousness. The new basic seizure classification is based on three key features: (1) where in the brain the seizure originates; (2) the individual's level of awareness during a seizure; and (3) other seizure features.[26]

① Seizures can be classified into an initial three categories depending on how they begin in the brain (eg, onset): (1) focal seizures (previously called partial seizures) that start in a network of cells on one side of the brain; (2) generalized seizures (previously called primary generalized) that start in a bilaterally distributed network (eg, a network encompassing both sides of the brain); and (3) unknown onset which can later be recategorized when it becomes clear how seizures begin in a particular individual's brain.[26] Understanding seizure onset is important, as it has significant treatment and prognostic implications affecting choice of seizure medication and eligibility for epilepsy surgery. Examples of this include patients with generalized-onset seizures who may have a seizure exacerbation when treated with certain ASMs (eg, treating childhood absence epilepsy with carbamazepine)[27] or patients with medication-resistant focal-onset seizures who may be good candidates for surgical resection, while those with generalized-onset seizures are not.

Focal Seizures

In general, focal seizures may be characterized by whether the patient retains awareness of themselves and their environment including external stimuli (eg, being asked questions) during the seizure, even if immobile and unable to talk or respond. When awareness is retained the seizure is termed a "focal aware seizure" corresponding to what has historically been termed "simple partial seizure." A focal impaired awareness seizure corresponds to the prior term "complex partial seizure" and is an appropriate classification if the person has impaired awareness at any time during the seizure (eg, they are aware in the beginning but lose awareness at the end, or if they have a vague idea of what is occurring and know that someone is speaking to them but respond inappropriately).[26]

Focal seizures can be further subgrouped by earliest most prominent motor sign (eg, automatisms, clonic, myoclonic) or nonmotor sign (eg, autonomic or sensory symptoms) at seizure onset. If motor signs are present, then some type of movement will occur during the seizure such as twitching and jerking (eg, myoclonus), stiffening (tonic contraction), or automatic movements (automatisms) such as smacking lips, rubbing hands, picking at clothes. Nonmotor signs include changes in sensation, emotions, thinking, or experience. The symptoms felt by the individual at the very beginning of a seizure is sometimes called an aura, although this term is now discouraged. Motor or nonmotor symptoms that may appear at onset are listed in Fig. 75-1.[26]

Focal seizures may propagate beyond one brain hemisphere to also involve the contralateral hemisphere. This seizure type is called “focal to bilateral tonic–clonic” and is a special seizure type which previously was called “partial onset with secondary generalization” or “secondarily generalized tonic–clonic (GTC) seizure.” The term “to bilateral” is preferred to distinguish this focal-onset seizure from a generalized-onset seizure. During this type of seizure, the person usually becomes unconscious and displays bilateral convulsive features such as tonic–clonic motor features.[26,28]

Focal aware seizures may manifest clinically in a variety of ways and can vary depending on where the abnormal firing occurs. For example, seizures manifesting as abnormal movements such as clonic movements (eg, twitching or jerking) of the arm, shoulder, face, or leg indicate seizure activity in motor pathways. Feelings of numbness or tingling indicate sensory or somatosensory involvement and may indicate parietal lobe involvement. Sensory symptoms can also include feelings of fear, depression, joy, anger, or memory phenomena such as feelings of familiarity (déjà vu) or unfamiliarity (jamais vu) that may indicate temporal lobe seizure activity. Visual disturbances or hallucinations may indicate seizure activity involving the occipital lobe, while ringing or buzzing sounds in the ears may indicate seizure activity in auditory areas of the brain. Autonomic symptoms such as sweating, salivation, or pallor indicate seizure activity in autonomic areas of the brain.[28,29]

Focal unaware seizures may manifest with any of the signs and symptoms described for focal aware seizures except that the patient does not retain awareness. They may still be able to perform routine tasks such as walking, but such movements are not purposeful or planned and after the event is over they may not recall their actions. The patient may be able to respond to questions during the seizure, although they may not respond appropriately. The degree of alteration in awareness and responsiveness may be so subtle that witnesses may not recognize that anything is overtly wrong. For example, they may simply display behavioral arrest and stare off into space for a minute. They may also display subtle automatisms such as lip smacking, chewing, or picking at their clothing without purpose. On the other hand, some patients may display extreme aberrations of behavior, and some are even mistakenly diagnosed as having psychotic episodes. After the seizure (postictal period), the patient may display altered consciousness, drowsiness, confusion, or even paranoia for a variable period of time and frequently go into a deep sleep.[28,29]

Generalized-Onset Seizures

Generalized-onset seizures start in a network that is bilaterally distributed to both brain hemispheres and have previously been referred to as primary generalized seizures. These types of seizures involve impaired awareness and are divided into motor and nonmotor (eg, absence) seizures. Generalized "absence" seizures are not synonymous with an "absent stare" which typically accompanies the behavioral arrest that occurs in other seizure types.[26]

Generalized-onset seizures can have a variety of motor symptoms with the major motor category being tonic–clonic. These generalized-onset tonic–clonic seizures were previously called "grand mal" seizures. During these seizures the patient experiences loss of consciousness, followed by a sudden sharp tonic contraction (stiffening) of muscles with a subsequent period of rigidity and clonic movements, oftentimes described as jerking of the arms and legs. During the seizure, the patient may cry or moan, due to muscles in the larynx being activated or they may lose sphincter control with bladder and/or bowel incontinence or bite their tongue. Postictally, after consciousness is regained, the patient may experience confusion, drowsiness, lack of coordination, soreness throughout the body, and amnesia for the event.[28,29]

It is important to remember that bilateral tonic–clonic seizures can also result from focal propagation to contralateral hemispheres and that these seizures must be differentiated from generalized-onset tonic–clonic seizures. Generalized manifestations of seizures can be asymmetrical or symmetrical, rendering the distinction from focal-onset seizures difficult, but certain distinguishing features such as very early motor or nonmotor signs that may be characteristic of focal-onset seizures, and characteristic findings on EEG aid in distinguishing between the two. Other forms of generalized motor seizures may happen but the generalized tonic–clonic (GTC) seizure is most common and most distinct.[6,28]

In contrast to other motor seizure categories in which there is a sudden onset of increased tone, a sudden loss of muscle tone occurs in *atonic seizures.* Atonic seizures are not preceded by myoclonic or tonic features and can be very brief. They may present as a head drop, the dropping of a limb, or a slumping to the ground (due to loss of postural tone). These patients often wear protective headware to prevent trauma and atonic seizures are one hallmark of Lennox–Gastaut syndrome.[6,28]

Typical generalized nonmotor seizures, aka "absence" seizures, can manifest as typical absence seizures, atypical absence, absence seizures with myoclonia, or absence seizures with eyelid myoclonia. Most commonly, typical absence seizures manifest as a sudden onset interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eyes indicating the abrupt onset and offset of impaired consciousness. The staring and behavioral arrest lasts 2 to 30 seconds during which time the patient is unaware of the environment and unresponsive. The patient has neither a warning that the seizure is going to occur, nor does the patient have postictal confusion or lethargy after the seizures. After cessation of the seizure, the patient will often return to the previous activity as if nothing had happened. These absence seizures generally occur in young children through adolescence. It is important to differentiate these seizures from focal unaware seizures; in general, absence-type seizures are much briefer than the staring spells associated with focal unaware seizures and have minimal postictal manifestations.[6,28,29]

Seizures of Unknown Onset

Seizures of unknown onset are classified based on presence of motor or nonmotor features; however, in some cases it may be impossible to classify a seizure at all. Although this should be a rare occurrence, in such cases this seizure would be an unclassified seizure.[26]

Classification of Epilepsies and Epilepsy Syndromes

A seizure is only a symptom that occurs within epilepsy; therefore, seizure classification is distinct from but related to the classification of epilepsies and epilepsy syndromes. The starting point of epilepsy classification is identification of the seizure type, understanding that some patients may have multiple different seizure types. After seizure types are determined, the epilepsy should be classified into one of four categories: (1) focal epilepsy in which a patient only has focal-onset seizures; (2) generalized epilepsy in which a patient displays evidence of only generalized-onset seizures; (3) combined generalized and focal epilepsy; and (4) unknown in which the epilepsy type is unknown (see Fig. 75-2).[6]

FIGURE 75-2

ILAE Framework for classification of the epilepsies. *(Reprinted, with permission, from Scheffer IE, Berkovic S, Capovilla G, et al. ILAE classification of the epilepsies: Position paper of the ILAE Commission for Classification and Terminology. Epilepsia. 2017;58(4):512–521.)*

After establishing the epilepsy type, an epilepsy syndrome should be determined if possible. In general, while knowing the etiology and specific comorbid characteristics of a patient with epilepsy is important during seizure and epilepsy classification, these parameters can be unknown and are not necessary. However, when determining epilepsy syndromes (the most specific level of epilepsy classification possible), knowing definitive etiology and specific comorbid characteristics is critical (see Fig. 75-2). Epilepsy syndromes are characterized by a known etiology and by a cluster of signs and symptoms including distinctive comorbidities such as intellectual and psychiatric dysfunction that customarily occur together. Other signs and symptoms include type of seizure, specific electroencephalogram (EEG) findings, specific imaging features, anatomy, precipitating factors, age of onset, severity, chronicity, and diurnal and circadian cycling.[6] Common epilepsy syndromes include childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), and juvenile myoclonic epilepsy (JME).[6] They are often grouped together and called the idiopathic generalized epilepsies (IGEs) or the genetic generalized epilepsies (GGEs). Other well-recognized syndromes are West syndrome, Lennox–Gastaut syndrome (LGS), and Dravet syndrome.[6]

Diagnosis

Epilepsy is a clinical diagnosis, meaning that it is made on the basis of medical signs and patient-reported symptoms, rather than any one diagnostic test. A person is considered to have epilepsy if they meet any of the following conditions: (1) at least two unprovoked (or reflex) seizures occurring greater than 24 hours apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (3) diagnosis of an epilepsy syndrome.[30]

Accurate diagnosis also depends on the neurologic examination and diagnostic techniques such as EEG and brain imaging. The neurologic examination is generally nonfocal, and focal findings may suggest a nonepilepsy diagnosis or help identify an epilepsy etiology (eg, stroke). The EEG can identify abnormal brain wave patterns that are associated with certain seizure types and epilepsy syndromes and is one of the most common and important diagnostic tests that can be performed for a patient with epilepsy. However, an abnormal epileptiform EEG is found in only approximately 50% of the patients who have epilepsy and sometimes several EEGs must be obtained before convincing epileptiformver activity is detected. Video EEG is the gold standard for diagnosing epilepsy and involves hospital admission to facilitate recording video and continuous EEG monitoring until the patient has a typical event. However, this is not the standard for most patients and is generally reserved for cases unresponsive to medication or difficult to characterize.[31,32]

Brain imaging with either a computed tomography scan (CT) or MRI can detect structural lesions that aid in the diagnosis of seizures and epilepsy types. A CT is commonly performed in patients who present after their first seizure, as a way to evaluate for a brain tumor, cerebral bleeding, or gross anatomical injury. An MRI is preferred for validation of an epilepsy diagnosis as it is the preferred imaging technique to identify more subtle structural abnormalities (eg, sclerosis in the mesial temporal lobes and traumatic brain injury).[32]

There are no diagnostic laboratory tests for epilepsy; however, in some cases, particularly following generalized convulsive seizures, serum prolactin levels obtained within 10 to 20 minutes can be transiently elevated.[33] Other laboratory tests can be done to rule out treatable causes of seizures (eg, hypoglycemia, altered electrolyte concentrations, infections) that do not represent epilepsy.

TREATMENT

Desired Outcomes

① ASM therapy is the mainstay of epilepsy treatment; however, all available ASMs are symptomatic treatments which only prevent seizures from occurring. None have been proven to have any disease modifying or antiepileptogenic properties and no ASMs are curative. Surgery is the only possibly curative therapy and only a select number of patients qualify for surgery (see section "Nonpharmacologic Therapy"). Therefore, the majority of patients with epilepsy will be on life-long ASM therapy. The goal of ASM therapy is eliminating the occurrence of seizures within the shortest possible duration of time and with minimal impact on QOL. In most patients the desired outcome is complete seizure freedom with little to no medication adverse effects. However, in 20% to 35% of patients, complete seizure freedom may not be possible[34] and more obtainable goals that balance seizure control with patient-specific QOL factors and wishes (eg, decrease in the number of seizures with minimized adverse effects) should be established.

General Approach to Treatment

When a patient presents after a single isolated seizure, one of three treatment decisions can be made: (1) treat, (2) possibly treat, or (3) do not treat, with the ultimate decision being based on the probability of the patient having a second seizure. The probability of recurrent seizures is higher if certain findings are present, including brain imaging abnormalities (eg, stroke, trauma, CNS infection, cerebral palsy, and other cognitive developmental disabilities), EEG with epileptiform abnormalities (characterized by spikes or sharp waves), or a nocturnal seizure.[35] For patients with any of the above findings present, the probability of seizure recurrence may be 2 to 2.5 times that of those without those findings.[35] The decision on whether to start ASM therapy after a single seizure depends on clinician judgment and available clinical evidence. Some clinicians choose to start ASM treatment after one seizure with a definite abnormal MRI or epileptiform EEG while others do not initiate treatment until a second seizure has occurred. In general, patients who have had two or more unprovoked seizures should be started on ASMs.[30,35]

② Once the decision to initiate therapy has been determined, accurate identification of seizure type and epilepsy diagnosis is critical for treatment, as an ASM must be effective for the specific seizure type and epilepsy, or epilepsy syndrome, being treated. For instance, if a patient is diagnosed with the epilepsy syndrome, childhood absence epilepsy (CAE), then an ASM that is effective for that syndrome (eg, ethosuximide) should be selected, and an ASM that may exacerbate that syndrome (eg, phenytoin or carbamazepine) should be avoided. Only after an accurate diagnosis is obtained, can a care plan, including selection and/or optimization of ASM therapy, be developed.[27]

③ During ASM selection, several possible first-choice agents are identified based on the type of epilepsy, and then narrowed down to an ideal single medication based on patient-specific characteristics including age, sex, susceptibility to adverse effects, comorbid medical conditions, interactions with other medications, ability to adhere to a prescribed regimen, and cost of therapy/insurance coverage (Table 75-1). Patient-specific characteristics must be taken into consideration as individuals may be better suited to receive one ASM over another. For instance, children may be more susceptible to neuropsychiatric adverse effects and ASMs with those effects should be avoided. Females with child-bearing potential should not be on ASMs with unacceptable teratogenicity, and ASMs with adverse cognitive effects should be avoided in older adults as they may be more susceptible. On the other hand, patients with comorbid conditions, such as migraine headache, bipolar disorder, or neuropathy, may benefit from the use of particular ASMs that can also treat those comorbid conditions (eg, topiramate for the treatment of epilepsy and migraine, lamotrigine for the treatment of epilepsy and bipolar, pregabalin for the treatment of epilepsy and neuropathy).

TABLE 75-1

Factors to Consider When Making ASM Selection

1. ASM efficacy for the specific seizure type, epilepsy, or epilepsy syndrome
2. Selection of an ASM that can also treat the patient's other comorbid conditions
3. Selection of an ASM with the most tolerable adverse effect profile, considering patient-specific factors including age and sex
4. Interactions with other medications
5. Ability to adhere to a prescribed regimen (eg, three or four times daily dosing) and insurance coverage, as this can affect ASM adherence and effectiveness
6. Need to quickly reach therapeutic levels

Pharmacokinetic interactions are a common complicating factor in ASM selection and an appreciation of pharmacokinetic variability is necessary when selecting therapy (Table 75-2). In general, ASM interactions can occur in any of the pharmacokinetic processes (eg, absorption, distribution, metabolism, or elimination); however, their effects on metabolic pathways are particularly complex and significantly affect management. Knowledge of ASM metabolic pathways as well as induction or inhibitory effects on liver enzymes (Table 75-3) can aid in ASM optimization. Caution should be used when ASMs are added to or withdrawn from a drug regimen.

Clobazam	CYP3A4; CYP2C19; CYP2B6	2	CYP3A4 (weak)	CYP2C9
Fenfluramine	CYP1A2; CYP2B6; CYP2D6	<25	None	None
Rufinamide	Hydrolysis	2	CYP3A4 (weak)	CYP2E1 (weak)
Stiripentol	CYP1A2, CYP2C19, CYP3A4	0.1	CYP1A2, CYP2B6; CYP3A4	CYP1A2, CYP2B6; CYP3A4; CYP 2C8/19
Vigabatrin	None	Almost completely	CYP2C9	None

CYP, cytochrome P450 isoenzyme system; GT, glucuronyltransferase; MHD, monohydroxy derivative, 10-OH-carbazepine.

Data from References 17–20, 23, 36–56.

When selecting ASM therapy, a patient's ability to adhere to a prescribed regimen and their insurance coverage are of extreme importance, as these factors can impact outcomes. For instance, a prescribed regimen requiring multiple daily doses may result in nonadherence for a patient who finds it difficult to remember to take medicines leading to decreased seizure control. Switching to an alternative with fewer daily doses may improve outcomes in that case. Similarly, an ASM that is not covered by insurance or is expensive may also promote nonadherence or adversely affect the patient by causing financial hardship. Ultimately, ASM effectiveness results from the interaction of all of these specific factors.

Optimizing Dose

④ Once an ASM has been selected, it should be initiated at an appropriate starting dose, and gradually titrated up to a therapeutic maintenance dose based on individual ASM recommendations (Table 75-4). Titration to an adequate therapeutic dose usually occurs over a few weeks and is necessary to allow the patient to slowly adjust to dose-related adverse effects. Some individuals, such as older adults who are sensitive to falls, sedation, and other neurocognitive adverse effects, need to have lower doses started and titrated more slowly. In such cases, titration can last over many weeks or months and may have a lower goal dose. In patients with multiple recent seizures, a therapeutic dose needs to be reached much more quickly, and a rapid titration over days instead of weeks is appropriate. For such patients, loading doses, either administered orally or intravenously, may be indicated. When used in this manner, it is important to select ASMs that can be administered safely as loading doses, as medications like lamotrigine and topiramate require slow titration and should not be used in patients who require loading to reach therapeutic levels quickly (Table 75-4).

TABLE 75-4

Antiseizure Medication Dosing and Target Serum Concentration Ranges

Generic Medication	Initial Total Daily Dose	Usual Effective TDD Range	FDA Recommended	Target Serum Concentration	Dosing Notes

Name (Brand Name)	(TTD)		Max TDD	Range	
First Generation					
Carbamazepine (Tegretol, Tegretol XR)	400 mg (>12 yrs) 200 mg (6-12 yrs) 10-20 mg/kg (<6 yrs)	400-1,200 mg (>12 yrs) 200-1,000 mg (6-12 yrs) 10-35 mg/kg (<6 yrs)	1,600 mg (>12 yrs) 1,000 mg (6-12 yrs) 35 mg/kg (<6 yrs)	4-12 mcg/mL (mg/L; 17-51 µmol/L)	Doses higher than FDA recommended max have been used in clinical practice.
Clonazepam (Klonopin)	Up to 1.5 mg (≥18 yrs) 0.01-0.03 mg/kg (<10 yrs or <30kg)	1-8 mg (≥18 yrs) 0.01-0.05 mg/kg (<10 yrs or <30 kg)	20 mg (≥18 yrs) 0.05 mg/kg (<10yrs or <30kg)	20-70 ng/mL (mcg/L; 63-222 nmol/L)	Initial adult TDD may be up to 1.5 mg/day although lower TDD are typically initiated (eg, 0.5-1 mg/day).
Ethosuximide (Zarontin)	500 mg (≥6 yrs) 250 mg (3-6 yrs)	500-1,500 mg (≥6 yrs) 20 mg/kg (3-6 yrs)	1,500 mg (All ages)	40-100 mcg/mL (mg/L; 283-708 µmol/L)	FDA recommended maximum TDD is not explicitly identified, but doses ≥ 1,500 mg should only be used with strict monitoring.
Phenobarbital (Various)	300 mg (≥18 yrs) 5 mg/kg (<18 yrs) (15-20 mg/kg LD)	300-600 mg (≥18 yrs) 4-8 mg/kg (<18 yrs)	600 mg (≥18 yrs) 300 mg (<18 yrs)	10-40 mcg/mL (mg/L; 43-172 µmol/L)	FDA recommended doses are not available but usual dose ranges and max doses listed here are commonly used in practice.
Phenytoin (Dilantin)	300 mg (≥18 yrs) 5mg/kg (<18 yrs) (15-20 mg/kg LD)	300-600 mg (≥18 yrs) 4-8 mg/kg (<18 yrs)	600 mg (≥18 yrs) 300 mg (<18 yrs)	Total: 10-20 mcg/mL (mg/L; 40-79 µmol/L) Unbound: 0.5-3 mcg/mL (mg/L; 2-12 µmol/L)	Patients > 6 yrs may require the minimum adult TDD of 300 mg; 600 mg is the maximum recommended TDD in adults; however, higher TDD may be used in practice if serum levels are still within therapeutic range.
Primidone (Mysoline)	100-125 mg (≥8 yrs)	750-1,000 mg (≥8 yrs)	2,000 mg (≥8 yrs)	5-10 mcg/mL (mg/L; 23-46 µmol/L)	
Valproic acid, Divalproex, Valproate (Depakene, Depakote DR, Depakote ER, Depacon)	10-15 mg/kg (≥10 yrs)	20-30 mg/kg (≥10 yrs)	60 mg/kg (≥10 yrs)	50-100 mcg/mL (mg/L; 347-693 µmol/L)	
Second Generation					

Felbamate (Felbatol)	1,200 mg (≥14 yrs) 15 mg/kg (2-14 yrs)	1200-3,600 mg (≥14 yrs) 15-45 mg/kg (2-14 yrs)	3,600 mg (≥14 yrs) 45 mg/kg (2-14 yrs)	30-60 mcg/mL (mg/L; 126-252 µmol/L)	Pediatric dosing listed is for LGS.
Gabapentin (Neurontin)	300-900 mg (≥12 yrs) 10-15 mg/kg (3-11 yrs)	900-1,800 mg (≥12 yrs) 25-40 mg/kg (3-11 yrs)	3,600 mg (≥12 yrs) 50 mg/kg (3-11 yrs)	2-20 mcg/mL (mg/L; 12-117 µmol/L)	In patients >12 yrs, TDDs up to 3,600 mg/day have been tolerated for short durations; TDD up to 4,800 mg day have been described in the literature.
Lamotrigine (Lamictal, Lamictal XR)	25 mg (>12 years) 0.3 mg/kg (2-12 yrs)	225-375 mg (>12 yrs) 4.5-7.5 mg/kg (2-12 yrs)	500 mg (>12 yrs) 300 mg (2-12 yrs)	4-20 mcg/mL (mg/L; 16-78 µmol/L)	Dosing recommendations differ if on VPA, CBZ, PB, PHT, PRM, or VPA; refer to PI for specific dose recommendations for patients on those concomitant ASMs.
Levetiracetam (Keppra, Keppra XR)	1,000 mg (≥16 yrs) 20 mg/kg (6-15 yrs) Varies by age (<6 yrs)	2,000-3,000 mg (≥16 yrs) 20-60 mg/kg (6-15 yrs) Varies by age (<6 yrs)	3,000 mg (≥16 yrs) 60 mg/kg (6-15 yrs) Varies by age (<6 yrs)	12-46 mcg/mL (mg/L; 70-270 µmol/L)	Refer to PI for specific age-based dose recommendations for <6 yrs; XR formulation is only approved for ages >12 years; an initial TDD of 500 mg can be used for older patients; FDA approved maximum doses are listed although higher doses have been used in clinical practice.
Oxcarbazepine (Trileptal, Oxtellar XR)	600 mg (>17 yrs) 8-10 mg/kg-max 600 mg (2-16 yrs)	1,200-2,400 mg (>17 yrs) 900-1,800 mg (2-16 yrs)	2,400 mg (>17 yrs) Varies by age (2-16 yrs)	3-35 mcg/mL (MHD) (mg/L; 12-138 µmol/L)	Pediatric dosing listed varies based on weight, refer to PI for specific weigh-based dose recommendations; XR formulation is approved for ages 6 and older.
Tiagabine (Gabitril)	4 mg if on other ASMs that are inducers and <4 mg if not on inducers (≥12 yrs)	32-56 mg if on other ASMs that are inducers and <32-56 mg if not on inducers (≥12 yrs)	56 mg if on other ASMs that are inducers and <56 mg if not on inducers (≥12 yrs)	0.02-0.2 mcg/mL (mg/L; 0.05-0.5 µmol/L)	Not FDA approved in patients under 12 years
Topiramate (Topamax, Trokendi XR)	25-50 mg (≥10 yrs) 25 mg (2-9 yrs)	200-400 mg (≥ 10 yrs) 150-400 mg based on weight (2-9 yrs)	400 mg (≥10 yrs) Varies based on weight (2-9 yrs)	5-20 mcg/mL (mg/L; 15-59 µmol/L)	Pediatric listed dosing varies based on weight; refer to PI for specific weight-based dose recommendations; XR formulation approved for ages 6 and up; maximum recommended TDD is 400 mg; however, up to 1,600 mg has been described for specific situations (eg, status epilepticus).
Zonisamide (Zonegran)	100 mg (>16 yrs)	200-400 mg (>16 yrs)	600 mg (> 16 yrs)	10-40 mcg/mL (mg/L; 47-188 µmol/L)	FDA approved pediatric dosing recommendations not available.
Third Generation					
Brivaracetam	100 mg (≥16	100-200 mg (≥16	200 mg (≥16 yrs)	Not defined	Pediatric dosing listed for patients <50 kg varies

(Briviact)	yrs) 50-100 mg if >50 kg or 1-3 mg/kg if <50 kg (1 mo – 15 yrs)	yrs) 50-200 mg if >50 kg or 1-6 mg/kg if < 50 kg (1 mo – 15 yrs)	Varies based on weight (1 mo- 15 yrs)		based on weight; refer to PI for specific weight-based dose recommendations.
Cenobamate (Xcopri)	12.5 mg (≥18 yrs)	200-400 mg (≥18 yrs)	400 mg (≥18 yrs)	Not defined	Not FDA approved in pediatrics.
Eslicarbazepine (Aptiom)	400 mg (≥18 yrs) 200-400 mg (4-17 yrs)	800-1,600 mg (≥18 yrs) 400-1,200 mg (4-17 yrs)	1,600 mg (≥18 yrs) 1200 mg (4-17 yrs)	Not defined	Pediatric dosing listed is weight-based; refer to PI for specific weight-based dose recommendations.
Lacosamide (Vimpat)	100-200 mg (>17 yrs) 100 mg if >50 kg and 2mg/kg if <50 kg (4-17 yrs)	200-400 mg (>17 yrs) 200-400 mg if >50 kg or 4-8 mg/kg if <50 kg (4-17 yrs)	400 mg (>17 yrs) 400 mg if >50 kg or 8 mg/kg if <50 kg (4-17 yrs)	Not defined	Dosing listed is for focal onset and generalized onset tonic–clonic seizures
Perampanel (Fycompa)	2 mg	8-12 mg	12 mg	Not defined	Dosing listed is for patients >4 yrs with focal onset seizures or >12 yrs with generalized onset tonic–clonic seizures.
Pregabalin (Lyrica)	150 mg (≥17 yrs) 2.5 mg/kg if >30 kg and 3.5 mg/kg between 11-29 kg (4-17 yrs)	150-600 mg (≥17 yrs) 2.5-10 mg/kg if >30kg and 3.5-14 mg/kg between 11-29 kg (4-17 yrs)	600 mg (≥17 yrs) 600 mg if >30kg and 14 mg/kg between 11 and 29 kg (4-17 yrs)	Not defined	
Third Generation with Indications for Specific Epilepsy Syndromes					
Cannabadiol (Epidiolex)	5 mg/kg (≥2 yrs)	10-20 mg/kg (≥2 yrs)	20 mg/kg (≥2 yrs)	Not defined	Dosing listed is for Dravet Syndrome and LGS.
Clobazam (Onfi)	5 mg if ≤ 30 kg and 10 mg if >30 kg (≥2 yrs)	5-20 mg if ≤30 kg and 10-40 mg if >30 kg (≥2 yrs)	20 mg if <30 kg and 40 mg if >30 kg (≥2 yrs)	0.03-0.3 ng/mL (mcg/L; 0.1-1.0 nmol/L)	Dosing listed is for LGS.
Fenfluramine (Fintepla)	0.2 mg/kg if not on STP and 0.1 mg/kg if on STP and CLB (≥2 yrs)	0.35 mg/kg if not on STP and 0.2mg/kg/day if on STP and CLB (≥2 yrs)	26 mg if not on STP and 17 mg if on STP and CLB (≥2 yrs)	Not defined	Dosing listed is for Dravet Syndrome.
Rufinamide (Banzel)	400-800 mg (≥17 yrs)	1,600-3,200 mg (≥17 yrs)	3,200 mg (≥17 yrs)	Not defined	Dosing listed is for LGS. FDA labeling states the efficacy of TDD <3,200 mg is unknown; however,

	10 mg/kg (1-16 yrs)	10-45 mg/kg (1-16 yrs)	3,200 mg (1-16 yrs)		doses <3,200 mg are commonly used in clinical practice.
Stiripentol (Diacomit)	50 mg/kg (≥2 yrs)	50 mg/kg (≥2 yrs)	3,000 mg (≥2 yrs)	4-22 mg/L (mcg/mL; 17-94 µmol/L)	Dosing listed is for patients with Dravet Syndrome who are also on CLB. STP should only be used in combination therapy with CLB.
Vigabatrin (Sabril)	1,000 mg (≥17 yrs) 350-500 mg depending on weight (2-16 yrs) 50 mg/kg (Infants)	1,000-3,000 mg (≥17 yrs) 1,050-2,000 mg depending on weight (2-16 yrs) 50-150 mg/kg (Infants)	3,000 mg (≥17 yrs) Varies by weight (2-16 yrs) 150 mg/kg (Infants)	0.8-36 mcg/mL (mg/L; 6-279 µmol/L)	Infant dosing listed is for infantile spasms; adult and non-infant pediatric dosing listed is for refractory focal seizures.

CLB, clobazam; CBZ, carbamazepine; DR, delayed-release; FDA, Food and Drug Administration; ER, extended-release; LD, loading dose; LGS, Lennox-Gastaut Syndrome; MHD, 10-monohydroxycarbazepine derivative; PB, phenobarbital; PHT, phenytoin; PI, prescribing information; PRM, primidone; STP, Stiripentol; TDD, total daily dose; yrs, years; VPA, valproate; XR, extended release.

Data from References 17–20,23,36–56.

Determining the optimal therapeutic dose for an individual takes into account treatment response and adverse medication reactions. If the patient is seizure free with no adverse reactions at a minimal therapeutic dose, then an optimal dose has been achieved and no further increases is necessary. If the patient continues to have seizures at a minimal or moderate-therapeutic dose, further titration to a maximum dose may be needed for optimal seizure control. If the patient continues to have seizures at a maximum dose, or if the patient experiences intolerable adverse reactions at any dose, adding a second ASM and then tapering and discontinuing the ineffective or intolerable first ASM is appropriate. Selecting an ASM with a different mechanism of action than the first intolerable or ineffective ASM may increase the likelihood of success with the second ASM, although there is no clear evidence to support this.[57]

5 In general, ASM monotherapy is preferred. However, if the patient continues to have seizures after switching to a second ASM as monotherapy at a therapeutic dose, dual ASM therapy may be necessary, and an adjunctive ASM should be gradually added. Selection of an adjunctive ASM with a different or complementary mechanism of action is recommended and is the basis behind rational polytherapy, although there is no clear evidence in humans to support this practice.[57] For individuals who continue to have seizures on dual ASM therapy, polytherapy with three or more agents can be considered. A suggested algorithm for a general approach to the treatment of epilepsy is shown in Fig. 75-3.

Nonpharmacologic Therapy

Pharmacologic therapy with ASMs is the mainstay of treatment for patients with epilepsy. However, approximately 20% to 35% of patients will not achieve adequate seizure control and seizures may be considered medication-resistant.[34] Nonpharmacologic therapies are available for these medication-resistant seizures, as well as for individuals with medication-responsive seizures in whom the benefits of nonpharmacologic therapies outweigh its risk. Nonpharmacologic therapy for epilepsy includes diet, vagus nerve stimulation (VNS), and surgery among other modalities.

The ketogenic diet, devised in the 1920s, is high in fat and low in carbohydrates and protein, which leads to a shift in metabolism resulting in acidosis and ketosis. As protein and calorie intake are set at levels that will meet requirements for growth, most of the calories provided come in the form of heavy cream and butter, although medium-chain triglycerides can be substituted for the dietary fats. Furthermore, no sugar is allowed, the overall fluids are controlled, and vitamins and minerals are supplemented. Given these restrictions, it requires strict control and parental adherence, as this diet is often used in childhood forms of epilepsy. Although some centers find the diet useful for medically refractory patients, particularly those with certain etiologies such as glucose transporter 1 (GLUT1) deficiency, others have found that it is poorly tolerated. Long-term effects include kidney stones, increased bone fractures, and adverse growth effects.[58] An international consensus statement has offered recommendations for employing various forms of the ketogenic diet which may be more tolerable, including the use of the modified Atkins diet and the Low Glycemic Index treatment.[59]

A VNS is an Food and Drug Administration (FDA) approved implanted medical device that is used as adjunctive therapy in reducing the frequency of seizures in adults and adolescents older than 12 years of age with focal seizures refractory to ASMs. It is also used off-label in the treatment of refractory primary generalized epilepsy. The mechanisms behind VNS's antiseizure actions are unknown. Human clinical studies have shown that VNS changes the cerebrospinal fluid (CSF) concentration of inhibitory and stimulatory neurotransmitters and activates specific areas of the brain that generate or regulate cortical seizure activity through increased blood flow. There is experimental evidence to suggest that the antiseizure effect of VNS is mediated by the locus coeruleus.[60]

The VNS is relatively safe and may have a positive effect on mood and behavior, often independent of seizure reduction.[61] The most common adverse reactions associated with stimulation are hoarseness, voice alteration, increased cough, pharyngitis, dyspnea, dyspepsia, and nausea. Serious adverse reactions reported include infection, nerve paralysis, hypoesthesia, facial paresis, left vocal cord paralysis, left facial paralysis, left recurrent laryngeal nerve injury, urinary retention, and low-grade fever. In the VNS studies, the percentage of patients who achieved a 50% or greater reduction in their seizure frequency (responders) ranged from 23% to 50% at 3 months.[62,63] The effects of VNS are not noted immediately, are more long term, and are also unlikely to lead to seizure freedom but may allow for reduced seizure frequency and reduced medication burden.

⑥ Surgery is the treatment of choice in select patients with refractory focal epilepsy, especially those with seizures originating from the temporal lobe. A randomized controlled trial, focusing on temporal lobe epilepsy, found that 58% of patients who underwent surgery were seizure free at 1 year compared to 8% of patients who did not undergo surgery.[64] A second randomized controlled study, to evaluate the efficacy of early surgery versus continued medical management in patients who had failed two ASM trials, showed that 11 of 15 patients who had undergone surgery were seizure free at 2-year follow-up, compared to none in the medical therapy group.[65] Certain factors have been found to predict positive outcomes in surgical patients including presence of a focal brain lesion on MRI, presence of unilateral mesial temporal sclerosis, presence of a localized temporal lobe positron emission tomography (PET) abnormality (even if brain MRI is normal), concordant EEG data showing location of ictal onset and shorter preoperative seizure duration.[66–68] The last finding is important to emphasize, as it is imperative to identify patients with treatment-resistant epilepsy and to refer them to an epilepsy center as soon as possible. Epilepsy surgery is not without risk, as learning and memory can be impaired postoperatively, and general intellectual abilities have also been affected in a small number of patients.[68] Patients may need to continue ASM therapy for a period of time following successful epilepsy surgery, but dosage reduction may be achievable.

Pharmacologic Therapy

ASM Efficacy

There are more than 24 FDA approved ASMs for the treatment of epilepsy in the United States. Only a subset of these are approved for monotherapy, and many are approved as add-on treatment only, in large part due to the difficulty in studying ASM monotherapy in randomized clinical trials. As such, many clinicians will use most ASMs off-label as monotherapy in clinical practice.

Clinical trials for ASM approval focus on their efficacy for either focal-onset epilepsies or specific epilepsy syndromes. Studies to directly compare the efficacy of individual ASMs are not practical and have not been conducted for many of these agents. All ASMs have comparable efficacy in focal-onset epilepsies, except for gabapentin, which is considered a weaker ASM and should be used as adjunctive therapy only. In generalized epilepsies and epilepsy syndromes, specific ASMs are FDA-approved (Table 75-5) or have recommendations for use in specific epilepsy types.

TABLE 75-5

Antiseizure Medications (ASMs)

ASM and Available Formulations	Postulated Mechanism of Action (MOA)/Indication	Advantages/Disadvantages	Interactions	Adverse Medication Reactions
First-Generation ASMs				
Carbamazepine Chewable tablet, ER tablet, liquid suspension	**MOA**: Enhances fast inactivation of voltage-gated sodium channels	**Advantages**: Useful in comorbid bipolar disorder and trigeminal neuralgia	**Effect of CBZ on ASMs**: CBZ is potent inducer of CYP3A4, CYP1A2, CYP2B6, CYP2C9/19; CBZ decreases or possibly decreases levels of brivaracetam, clonazepam, eslicarbazepine, ethosuximide,	**BOXED WARNING**: Increased risk of SJS/TEN with HLA-B*1502 allele; aplastic anemia and agranulocytosis **Common**: CNS effects including diplopia, dizziness, drowsiness; unsteadiness, lethargy; hyponatremia from SIADH

			felbamate, lacosamide, lamotrigine, oxcarbazepine, perampanel, phenytoin, rufinamide, stiripentol tiagabine, topiramate, valproate, zonisamide	
	Indication: Monotherapy/adjunctive therapy for focal onset, TC, and mixed seizure types except for absence seizures	**Disadvantages**: Avoid in absence epilepsy as it worsens other seizure types in those patient;; screening required for those at increased risk SJS/TEN in HLA-B*1502 and HLA-A*3101 allele (eg, specific Asian groups); avoid if prior rash with other ASMs due to possible cross-reaction auto-inducer; active metabolite carbamazepine 10,11 epoxide contributes to idiosyncratic adverse reactions; avoid in patients with history of bone marrow depression or sensitivity to tricyclic compounds; cannot use within 14 days of MAO inhibitor; can cause fetal harm	**Effect of ASMs on CBZ**: Cenobamate, eslicarbazepine, felbamate, phenobarbital, phenytoin, primidone, rufinamide may decrease CBZ levels; brivaracetam, felbamate, valproate may increase carbamazepine-10,11 epoxide levels; vigabatrin may increase CBZ levels	**Serious but rare**: Other blood dyscrasias including thrombocytopenia, leukopenia; DRESS; increased intraocular pressure; cardiovascular effects including 2nd and 3rd degree AV heart block; hepatotoxicity; genitourinary effects: nephrotoxicity
			Others (partial list): CYP3A4 inhibitors/inducers may increase/decrease CBZ levels; CBZ may decrease levels of hormonal contraceptives; do not administer with other liquid agents due to possibility of precipitate occurrence	**Long term**: Hyponatremia from SIADH; metabolic bone disease including osteoporosis, osteopenia, osteomalacia
Clonazepam (Schedule IV) Tablet, ODT	**MOA**: Binds $GABA_A$ receptor and potentiates GABA by modulating chloride conductance	**Advantages**: useful when there is a need for a benzodiazepine with long half-life	**Effect of clonazepam on ASMs**: Clonazepam may affect levels of phenytoin	**BOXED WARNING**: Concomitant use with opioids may result in profound sedation, respiratory depression, coma, and death. **Common**: CNS effects including impairment of cognitive and motor performance due to sedation and ataxia; behavior problems; paradoxical reactions such as agitation,

				irritability, aggression, anxiety, anger, nightmares, hallucinations and psychoses
	Indication: Monotherapy/adjunctive therapy for LGS (petit mal variant), akinetic, myoclonic, and absence seizures	**Disadvantage**: May increase TC seizures when used in mixed seizure types; tolerance and dependence may occur; risk of respiratory depression which is increased when used with other CNS depressants including opioids; contraindicated in acute narrow angle glaucoma and severe hepatic impairment; metabolites may accumulate with impaired renal function and may require dose adjustment; some loss of effect may occur after 3 months; withdrawal symptoms including status epilepticus may occur after discontinuation; may increase hypersalivation; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on clonazepam**: Carbamazepine, lamotrigine, phenobarbital, phenytoin may decrease clonazepam levels; vigabatrin increases clonazepam, clonazepam may be affected by other enzyme inducing or enzyme-inhibiting ASMs **Other (partial list):** use with opioids increase risk of respiratory depression	**Serious but rare**: Blood dyscrasias including leukopenia, thrombocytopenia, eosinophilia; respiratory depression; hepatomegaly; muscle weakness **Long term**: Physiologic dependence; hair loss; hirsutism; ankle and facial edema
Ethosuximide (ETX) Capsule, liquid solution	**MOA**: Inhibition of T-type calcium channels	**Advantages**: Medication of choice for absence seizures	**Effect of ETX on ASMs**: ETX may affect levels of carbamazepine, phenobarbital, phenytoin, primidone, valproate	**Common**: GI distress including nausea/vomiting, cramps diarrhea; epigastric and abdominal pain; anorexia and weight loss; CNS effects including lethargy, fatigue, drowsiness, dizziness, ataxia
	Indication: Monotherapy and adjunctive therapy for absence seizures in patients ≥3 years of age	**Disadvantages**: May worsen generalized TC seizures and other seizure types when used alone in mixed types of epilepsy; contraindicated in those with allergies to succinimides; may cause fetal harm; use with caution in hepatic/renal dysfunction	**Effect of ASMs on ETX**: Valproate may increase or decrease ETX levels	**Serious but rare**: Blood dyscrasias including leukopenia, agranulocytosis, pancytopenia, eosinophilia; rash including SJS; DRESS; hepatic/renal dysfunction; lupus erythematosus; psychiatric abnormalities including night terrors and paranoid psychosis **Long-term**: Behavioral changes
Phenobarbital (PB) (Schedule III) Tablet, elixir, injectable	**MOA**: Binds GABA$_A$ receptor and potentiates GABA by modulating chloride conductance	**Advantages**: Easily available world-wide; extensive knowledge and experience with PHB use despite not being FDA approved as PHB developed in early 1900s prior to	**Effect of PB on ASMs**: PB is inducer of CYP1A2, CYP2C9, CYP2C19, CYP3A4. PB may	**Common**: CNS effects including residual sedation or "hangover," impaired cognition, drowsiness,

solution		establishment of FDA and current regulatory practices	decrease levels of carbamazepine, eslicarbazepine, ethosuximide, felbamate, lacosamide, lamotrigine, oxcarbazepine, perampanel, phenytoin, rufinamide, stiripentol, tiagabine, topiramate, valproate, zonisamide	dizziness, vertigo, ataxia, headache, sleep disturbance; paroxysmal effects including excitement, irritability and hyperactivity in older adults and children; GI effects including epigastric pain, nausea, vomiting, diarrhea and constipation
	Indication: Not FDA approved; used for focal onset and generalized seizures	**Disadvantages**: Tolerance and dependence may occur; slow taper needed when discontinuing after prolonged use; use with other CNS depressants may produce additive CNS effects; may cause respiratory depression; can cause fetal harm	**Effect of ASMs on PB**: Cenobamate, felbamate, rufinamide, valproate may increase PB levels; phenytoin may increase or decrease PB levels	**Serious but rare**: Respiratory depression and apnea; rash (SJS, TEN); cardiac effects including bradycardia, hypotension with IV administration, syncope; hepatotoxicity; megaloblastic anemia; apnea and hypoventilation
			Other (partial list): PB may decrease levels of oral contraceptives	**Long term**: Behavioral changes; connective tissue disorder; intellectual blunting; metabolic bone disease (Rickets, osteopenia, osteoporosis, osteomalacia); folate deficiency (with megaloblastic anemia)
Phenytoin (PHT) ER capsule; liquid suspension; injectable; chewable tablet (Fosphenytoin, a prodrug desterified by esterases in the blood to phenytoin, also available as injectable solution only)	**MOA**: Enhances fast inactivation of voltage-gated sodium channels; inhibits persistent sodium current (I_{NAP}) and increases threshold for action potential firing	**Advantages**: May be orally or intravenously loaded in patients who require rapid steady-state serum levels; ER formulation useful in non-adherence as dosed once daily	**Effect of PHT on ASMs**: PHT may decreases levels of brivaracetam, carbamazepine, cenobamate, clonazepam, eslicarbazepine, felbamate, ethosuximide, felbamate, lacosamide, lamotrigine, oxcarbazepine, perampanel, rufinamide, stiripentol, tiagabine, topiramate, valproate, zonisamide	**Common**: CNS effects including ataxia, nystagmus, slurred speech, decreased coordination, mental confusion, dizziness, insomnia, transient nervousness, headaches
	Indication:	**Disadvantages**: May aggravate seizures in	**Effect of ASMs on**	**Serious but rare**: Blood

	Monotherapy/adjunctive therapy for focal onset psychomotor seizures and TC seizures; prevention or treatment of seizures during or after neurosurgery, severe TBI, status epilepticus	patients with absence seizures; can increase blood sugar levels in diabetes; HLA-B*1502 may be a risk factor for the development of SJS/TEN in patients of Asian ancestry; CYP2C9*3 carriers may increase development of SCARS; monitoring of free phenytoin levels required in renal, hepatic impairment, hypoalbuminemia, and pregnancy; compromised absorption with concomitant tube feeds; dose adjustments required to switch between free acid and sodium salt formulations; phenytoin dose adjustments needed in older adults due to decreased clearance; may exacerbate porphyria	**PHT**: Carbamazepine, eslicarbazepine, vigabatrin may decrease PHT levels; brivaracetam, cenobamate, ethosuximide, felbamate, methsuximide, oxcarbazepine, rufinamide, topiramate may increase PHT levels; phenobarbital, valproate may increase or decrease PHT levels	dyscrasias including thrombocytopenia, leukopenia, granulocytopenia, agranulocytosis, pancytopenia; lymphadenopathy; rash (SJS/TEN/SCARS); DRESS; hepatotoxicity; angioedema: bradycardia/cardiac arrest; purple glove syndrome with IV administration
			Other (partial list): PHT can substantially reduce delavirdine concentrations and cause loss of virologic response and resistance; may decrease contraceptive levels, may increase/decrease PT/INR when given with warfarin	**Long term**: Connective tissue changes including skin thickening, gingival hyperplasia, coarsening of facial features, enlargement of lips; hirsutism; metabolic bone disease (osteoporosis, osteopenia, osteomalacia); peripheral neuropathy; cerebellar atrophy; folate deficiency (with megaloblastic anemia)
Primidone (PRM) Tablet	**MOA**: Prodrug converted to active metabolite phenylethylmalonamide-amide (PEMA) and phenobarbital with same mechanism of action	**Advantages**: Useful in patients with essential tremor	**Effect of PRM on ASMs**: PRM may decrease levels of carbamazepine, eslicarbazepine, ethosuximide, felbamate, lacosamide, lamotrigine, oxcarbazepine, perampanel, phenytoin, rufinamide, stiripentol, tiagabine, topiramate, valproate, zonisamide	**Common**: CNS effects including ataxia, vertigo, nystagmus, diplopia, drowsiness, fatigue; GI effects including nausea/vomiting, anorexia, fatigue; emotional disturbances including hyperirritability **Serious but rare**: Blood dyscrasias including granulocytopenia, agranulocytosis; rash (SJS, TEN); liver dysfunction
	Indication: Monotherapy/adjunctive therapy for focal onset and TC seizures	**Disadvantages**: Contraindicated in porphyria	**Effect of ASMs on PRM**: Valproate may increase PRM levels; phenytoin may increase	**Long term**: Behavioral changes; intellectual blunting; connective tissue disorder; metabolic bone

			or decreases PRM levels; carbamazepine, eslicarbazepine may affect levels	disease (rickets, osteomalacia); folate deficiency (with megaloblastic anemia)
Valproate (VPA) Divalproex DR sprinkle capsule and tablet, Divalproex ER 24-hour tablet, valproic acid IR capsule, valproate sodium injectable solution	**MOA:** Likely potentiates GABAergic transmission among multiple other unknown mechanisms	**Advantages**: Useful in comorbid bipolar disorder and migraine; commonly used in all age groups including ages <10 years	**Effect of VPA on ASMs**: VPA may increase levels of eslicarbazepine, ethosuximide, felbamate, lamotrigine, oxcarbazepine, phenytoin, phenobarbital, rufinamide, tiagabine, topiramate, zonisamide **Effect of ASMs on VPA**: Carbamazepine, phenobarbital, phenytoin, primidone may decrease VPA levels; felbamate may increase VPA levelsmide	**BOXED WARNING**: hepatotoxicity especially for children <2 years of age and with mitochondrial disorders; fetal risk including neural tube defects, other major malformations, and decreased IQ; pancreatitis including fatal hemorrhagic pancreatitis **Common**: GI effects including abdominal pain/GI upset (worse with valproic acid IR), constipation, diarrhea, anorexia, increased appetite, weight gain, nausea/vomiting; CNS effects including blurred vision, ataxia, dizziness, headache, insomnia, nystagmus, somnolence, thinking abnormal, tremor; dose dependent thrombocytopenia (>100 mg/mL)
	Indication: Monotherapy/adjunctive therapy for focal onset and multiple seizure types for patients ≥10 years of age; monotherapy/adjunctive therapy for absence seizures in patients ≥10 years of age	**Disadvantages**: Contraindicated in significant hepatic dysfunction, mitochondrial disorders caused by DNA polymerase γ (POLG) mutations, urea cycle disorders; use with caution in pancreatitis, bleeding and other hematopoietic disorders; risk of hyperammonemia with and without encephalopathy associated with concomitant topiramate use; pregnancy category D—contraindicated in women of childbearing potential and pregnancy category X for pregnant patients treated for migraine prophylaxis		**Serious but rare**: Hyperammonemia with and without encephalopathy; hypothermia with and without hyperammonemia; DRESS; bleeding and other hematopoietic disorders
			Other (partial list): estrogen OCP may affect VPA levels	**Long-term**: Hair and nail changes including alopecia, hirsutism, hair texture and color changes, nail and nail bed disorders; irregular

				menses and polycystic ovary-like syndrome; weight gain; cerebral pseudoatrophy; osteoporosis and osteopenia
Second-Generation ASMs				
Felbamate (**FBM**) Tablet, liquid suspension	**MOA**: Antagonizes NMDA glutamate receptor; binds weakly to $GABA_A$ receptor and possibly augments GABAergic transmission	**Advantages**: May be useful in refractory epilepsy	**Effect of FBM on ASMs**: FBM may decrease carbamazepine levels; FBM may increase carbamazepine-epoxide, phenobarbital, phenytoin, valproate levels	**BOXED WARNING**: Irreversible fatal aplastic anemia aplastic anemia with greater risk in females, or history of cytopenia, ASM allergy or significant toxicity, viral infection, and/or immunologic problems; acute liver failure Aplastic anemia with reported onset between 5-30 weeks; acute liver failure with reported onset occurring in 5 weeks **Common**: GI effects including anorexia, vomiting, nausea; CNS effects including insomnia, headache, dizziness, somnolence
	Indication: Monotherapy/adjunctive therapy for focal onset seizures with and without TC seizures in patients ≥14 years; adjunctive therapy for focal onset and generalized seizures associated with LGS in patients aged 2-14	**Disadvantages**: For severe refractory epilepsy ONLY; contraindicated in patients with hepatic dysfunction, history of blood dyscrasias; use with caution in patients with renal dysfunction; available only through special access program; pregnancy category C	**Effect of ASMs on FBM**: Carbamazepine, phenobarbital, phenytoin, primidone may decrease FBM levels; valproate does not affect FBM levels to a clinically significant degree	
			Other (partial list): Estrogen OCP levels not affected	
Gabapentin (GBP) Tablet, capsule, oral solution	**MOA**: Binds to presynaptic α2δ subunit of calcium channels with unknown antiseizure effect	**Advantages**: Useful in post-herpetic neuralgia, chronic pain, and neuropathy; fewinteractions	**Effect of GBP on ASMs**: no significant effects	**Common**: CNS effects including somnolence, dizziness, ataxia, fatigue, nystagmus; peripheral edema and weight gain; GI effects including nausea/vomiting
	Indication: Adjunctive therapy for focal onset seizures with and without TC seizures in patients ≥3 years	**Disadvantages**: Considered weakly efficacious; potential abuse when taken with opioids; withdrawal reaction characterized by anxiety, insomnia, nausea, sweating, and increased pain; absorption may be impaired for doses >1,200 mg; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on GBP**: No significant effects	**Serious but rare**: Anaphylaxis, angioedema, DRESS, neuropsychiatric symptoms in children 3 to 12 years of age **Long-term**: Weight gain, peripheral edema
Lamotrigine	**MOA**: Enhances fast	**Advantages**: Useful in bipolar disease; XR	**Effect of LTG on**	**BOXED WARNING**: Rash

(LTG) Tablet, chewable tablet[a], ODT[a], XR tablet[a]	inactivation of voltage-gated sodium channels	useful in non-adherence as dosed once daily	**ASMs**: No significant effects	including SJS, TEN with increased risk if given with valproate, exceeding recommended initial dose or dose escalation
	Indication: Adjunctive therapy in focal onset and TC seizures, generalized seizures of LGS in patients ≥2 years of age; monotherapy in patients with focal-onset seizures ≥16 years of age	**Disadvantages**: Slow titration required to avoid rash including SJS; rash more likely to occur if patient with prior rash to other ASM and concomitant use of valproic acid; rash incidence higher in children; may exacerbate myoclonus; dosage adjustment required in patients with moderate and severe liver impairment; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on LTG**: Carbamazepine, cenobamate, oxcarbazepine, phenytoin, phenobarbital, primidone, rufinamide may decrease LTG levels; Cannabidiol increases LTG and valproate increases LTG levels by 2×	**Common**: CNS effects including dizziness, headache, diplopia, ataxia, blurred vision, somnolence, tremor; GI effects including nausea/vomiting, abdominal pain, diarrhea; other effects including rhinitis, pharyngitis, infection, fever; rash
			Other (partial list): estrogen OCPs may decrease LTG by 50%	**Serious but rare**: DRESS; blood dyscrasias; hemophagocytic lymphohistiocytosis (HLH)' Rash usually appears after 3-4 weeks of therapy and is typically generalized, erythematous, and morbilliform but can progress to SJS
Levetiracetam (LEV) Tablet, XR tablet[a], injectable solution	**MOA**: Binds to and selectively inhibits synaptic vesicle $SV2_A$ protein thereby preventing neurotransmitter release **Indication**: Adjunctive therapy for focal onset seizures in patients >14 months, myoclonic seizures in patients with JME ≥12 years of age, and generalized TC seizures in patients ≥6 years of age with generalized epilepsy	**Advantages**: Minimal interactions; XR useful in non-adherence as dosed once daily **Disadvantages**: May worsen depression, PTSD, anxiety, thought disorders; must dose adjust in dialysis/renal failure; pregnancy category C	**Effect of LEV on ASMs**: No significant effects	**Common**: CNS effects including somnolence, fatigue; behavior effects including aggression, agitation, anger, anxiety, apathy, depersonalization, depression, emotional lability, hostility, irritability **Serious but rare**: Psychosis, hallucinations
			Effect of ASMs on LEV: No significant effects	
Oxcarbazepine (OXC) Tablet, tablet	**MOA**: Enhances fast inactivation of voltage-gated sodium channels	**Advantages**: Useful in bipolar disorder; ER useful in non-adherence as dosed once daily	**Effects of OXC on ASMs**: OXC is inhibitor of CYP2C19 and inducer of	**Common**: CNS effects including dizziness, somnolence, diplopia,

ER[a], liquid suspension[a]			CYP3A4/5; OXC may decrease lamotrigine levels through UGT induction and decrease perampane levels; OXC may increase phenytoin levels	fatigue, ataxia, abnormal vision, headache, nystagmus, tremor; GI effects including nausea, vomiting; hyponatremia due to SIADH; rash
	Indication: Monotherapy/adjunctive therapy for focal onset seizures in patients ≥4 years of age; adjunctive therapy for focal onset seizures in patients ≥2 years of age	**Disadvantages**: Higher incidence of hyponatremia, (as high as 25%); HLA-B*1502 in Asians may increase SJS or TEN risk; may require slower titration in renal impairment; active MHD metabolite may decrease in pregnancy; no adequate data in pregnant patients—may cause fetal harm	**Effect of ASMs on OXC**: Carbamazepine, phenobarbital, phenytoin, primidone may decrease levels of OXC active metabolites; valproate may increase levels of OXC **Other (partial list)**: OXC may decrease estrogen OCP levels	**Serious but rare**: SJS, TEN; DRESS; blood dyscrasias
Tiagabine (TGB) Tablet	**MOA**: Inhibitor of GABA reuptake transporter GAT1	**Advantages**: none noted	**Effect of TGB on ASMs**: TGB may decrease VPA levels by 10%	**Common**: CNS effects including dizziness, lightheadedness, somnolence, thinking abnormal; behavior effects including asthenia, lack of energy, nervousness, irritability, difficulty with concentration or attention; GI effects including abdominal pain, nausea and vomiting
	Indication: Adjunctive therapy for focal onset seizures in patients ≥12 years of age	**Disadvantages**: Has been associated with new onset seizure, status epilepticus, and exacerbation of EEG abnormalities in those with existing epilepsy; dosage reduction may be necessary in patients with liver disease; pregnancy category	**Effects of ASMs on TGB**: Carbamazepine, phenobarbital, phenytoin, primidone increases TGB clearance by 60% and may decrease TGB levels; valproate may increase TGB levels by 40%	**Serious but rare**: Increase in generalized seizures and non-convulsive SE in patients with refractory epilepsy; occurrence of seizures and SE in patients without epilepsy; moderately severe to incapacitating generalized weakness; exacerbation of EEG abnormalities; rash including SJS **Long-term**: Possibility of long-term ophthalmologic effects
Topiramate	**MOA**: Antagonizes	**Advantages**: Useful in comorbid migraine	**Effect of TPM on**	**Common**: CNS effects

(TPM) Sprinkle capsule, tablet, XR tablet, capsule, capsule ER	voltage-gated sodium channel; binds to GABA$_A$ receptor and augments GABAergic transmission, antagonizes AMPA/kainate glutamate receptor, weak carbonic anhydrase inhibitor	and obesity; XR useful in non-adherence as dosed once daily	**ASMs**: TPM is weak inhibitor of CYP2C19 and inducer of CYP3A4; TPM may increase or decrease ASMs metabolized by CYP2C19 and 3A4 including felbamate and topiramate	including fatigue, difficulty concentrating, confusion, language problems, tremor paresthesias; behavioral effects including nervousness, anxiety
	Indication: Monotherapy/adjunctive therapy for focal onset seizures or primary generalized TC seizures in patients ≥2 years of age; adjunctive therapy for patients with LGS ≥2 years of age	**Disadvantages**: Avoid in patients with preexisting cognitive issues; renally dose adjust with CrCl <70 mL/min (1.17 mL/s); can cause fetal harm	**Effect of ASMs on TPM**: Carbamazepine, phenobarbital, phenytoin, primidone may decrease TPM levels; valproate may increase TPM levels **Other (partial list):** TPM at higher doses may decrease estrogen OCP levels	**Serious but rare**: Renal stones, glaucoma, hypo/erthermia, oligohidrosis, metabolic acidosis, SJS, TEN, and hyperammonemia with and without encephalopathy when used with valproate **Long term**: Weight loss; renal stones; metabolic acidosis
Zonisamide (ZON) Capsule	**MOA**: Enhances fast inactivation of voltage-gated sodium channels; inhibits T-type calcium channels; weak carbonic anhydrase inhibitor	**Advantages**: Useful in tremor; useful in non-adherence as dosed once daily	**Effect of ZON on ASMs**: no significant DDIs	**Common**: CNS effects including sedation, ataxia, confusion, depression, difficulty concentrating, word-finding difficulties
	Indication: Adjunctive therapy for focal onset seizures in adults	**Disadvantages**: Contraindicated in those with sulfa allergy; dose efficacy may plateau at 400mg; should not be used in renal failure due to increases in SCr and BUN and possible effects on GFR; pregnancy category C	**Effect of ASMs on ZON**: CYP3A4 inhibitors or inducers may alter ZON levels; carbamazepine, phenobarbital, phenytoin, valproate may decrease ZON levels	**Serious but rare**: Oligohidrosis and hyperthermia; renal stones; metabolic acidosis; rash (SJS, TEN); DRESS; fulminant hepatic necrosis; blood dyscrasias **Long term**: Weight loss; renal stones; metabolic acidosis
Third-Generation ASMs				
Brivaracetam (BRV, Schedule V) Tablet, oral Solution, injection Solution	**MOA**: Binds to and selectively inhibits synaptic vesicle SV2$_A$ protein thereby preventing neurotransmitter release	**Advantages**: Can consider converting well-controlled patients from levetiracetam if intolerable psychiatric adverse reactions	**Effect of BRV on ASMs**: BRV may increase carbamazepine metabolite; BRV may increase phenytoin levels; no added therapeutic benefit when given with	**Common**: CNS effects including sedation, fatigue, ataxia, nystagmus; behavioral effects including irritability, aggressive behavior, anxiety, agitation, restlessness, tearfulness, apathy, altered mood, mood

			levetiracetam	swings, hyperactivity, adjustment disorder; GI effects including nausea, vomiting
	Indication: Monotherapy/adjunctive therapy for focal onset seizures in patients ≥1 month of age; injection solution approved for ≥ 16 years of age	**Disadvantages**: Dosage adjustments required in hepatic impairment; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on BRV**: CYP2C19 inhibitors may alter BRV levels **Other (partial list)**: rifampin will reduce BRV levels	**Serious but rare**: Angioedema; bronchospasm; decreased neutrophils; psychosis and depression; hematologic abnormalities including leukopenia and neutropenia
Cenobamate (CBM, Schedule V) Tablet	**MOA**: Inhibition of voltage-gated sodium channels; positive allosteric modulator of GABA$_A$ ion channel	**Advantages**: none	**Effect of CBM on ASMs**: CBM is a CYP2C19, CYP2B6, CYP3A inhibitor and may increase substrate levels; CBM is a CY2B6, CYPC8, CYP3A4 inducer and may decrease substrate levels; CBM may increase phenytoin, phenobarbital, clobazam concentrations; CBM may decrease lamotrigine, carbamazepine concentrations; CBM does not affect valproic acid, levetiracetam, or lacosamide	**Common**: CNS effects including somnolence, dizziness, fatigue, diplopia, headache; dizziness and disturbance in gait and coordination; cognitive dysfunction including memory impairment, disturbance in attention, confusional state, slowness of thought; vision changes including diplopia, blurred vision, and impaired vision; laboratory abnormalities including hepatic transaminases, potassium elevation
	Indication: Monotherapy/adjunctive therapy for focal-onset seizures in adults	**Disadvantages**: must be slowly titrated q2weeks to avoid DRESS; contraindicated in Familial Short QT syndrome; caution when administering with other medications that shorten QT interval; use with caution and dose reduce in hepatic and renal impairment; use not recommended in end-stage hepatic or renal disease; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on CBM**: phenytoin may decrease CBM; valproate, phenobarbital, carbamazepine do not significantly impact CBM **Other (partial list)**: CBM may decrease estrogen OCP levels; additive risk with other medications that shorten the QT interval; use with CNS depressants increase	**Serious but rare**: DRESS with fast titration (weekly intervals); QT interval shortening; appendicitis

			CNS toxicity	
Eslicarbazepine (ESL) Tablet	**MOA**: Selectively enhances fast inactivation of voltage-gated sodium channels	**Advantages**: Useful in non-adherence as dosed once daily	**Effect of ESL on ASMs**: Inhibitor of CYP2C19; ESL may affect carbamazepine, perampanel, phenytoin, phenobarbital, primidone levels	**Common**: CNS effects including dizziness, somnolence, nausea, headache, diplopia, fatigue, vertigo, ataxia, blurred vision, tremor; hyponatremia due to SIADH; rash
	Indication: Monotherapy or adjunctive therapy for focal onset seizures in patients ≥4 years of age	**Disadvantages**: Avoid in severe hepatic impairment; dose adjustment in renal failure; avoid concomitant use with carbamazepine and oxcarbazepine; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on ESL**: Carbamazepine, phenobarbital, primidone, and phenytoin may decrease ESL levels **Other (partial list)**: ESL decreases estrogen OCP levels	**Serious but rare**: SJS; anaphylaxis, angioedema, DRESS; cardiac effects including prolonged PR interval, AV block; hepatotoxicity; blood dyscrasias **Long-term**: Hyponatremia
Lacosamide (LCM) (Schedule V) Tablet, oral solution, injectable solution	**MOA**: Selectively enhances slow inactivation of voltage-gated sodium channels	**Advantages**: Minimal interactions	**Effect of LCM on ASMs**: LCM is a potential CYP2C19 inhibitor but no clinically significant effects of LCM on other ASMs have been observed **Effect of ASMs on LCM**: LCM is a substrate of CYP3A4, CYP2C9, and CYP2C19; carbamazepine, phenytoin, phenobarbital, primidone may decrease LCM levels by 15-20% **Other (partial list)**: LCM may increase levels of strong CYP3A4 or CYP2C9 inhibitors in renal or hepatically impaired patients; risk of cardiac abnormalities increased with concomitant medications that affect cardiac conduction	**Common**: CNS effects including diplopia, headache, nausea, somnolence, dizziness, ataxia; GI effects including constipation, diarrhea, nausea, vomiting, dyspepsia, dry mouth, oral hypoesthesia/paresthesia; laboratory abnormalities including LFT elevations
	Indication: Monotherapy/adjunctive therapy for focal onset seizures in patients ≥4 years of age	**Disadvantages**: Avoid in 3rd degree heart block; must obtain ECG prior to intravenous infusion; use with caution in patients with underlying proarrhythmic conditions or on concomitant medications that affect cardiac conduction; not recommended in severe hepatic impairment; requires dose adjustment in renal impairment; oral solution contains phenylalanine and is a risk in patients with phenylketonuria no adequate data in pregnancy - may cause fetal harm		**Serious but rare**: Cardiac effects including AV conduction abnormalities, prolonged PR interval, atrial arrhythmias, syncope (especially in patients with diabetes), DRESS and hypersensitivity reactions; blood abnormalities including neutropenia and anemia
Perampanel (PER) (Schedule III) Tablet, oral	**MOA**: Selectively and noncompetitively antagonizes AMPA	**Advantages**: Useful in mixed seizure types; useful in non-adherence as dosed once daily	**Effect of PER on ASMs**: PER is a modest enzyme inducer at high	**BOXED WARNING**: Aggression, hostility, irritability, anger, and

suspension	glutamate receptor on post-synaptic neuron		doses	homicidal ideation
	Indication: Monotherapy for focal onset seizures in patients ≥4 years of age; adjunctive therapy for TC seizures in patients ≥12 years of age	**Disadvantages**: Avoid in active psychosis or unstable recurrent affective disorders with significant hostility or aggressive behavior; avoid in severe hepatic/renal impairment or hemodialysis; no adequate data in pregnancy - may cause fetal harm	**Effect of ASMs on PER**: carbamazepine, eslicarbazepine, oxcarbazepine, phenobarbital, phenytoin, primidone, topiramate decrease PER levels; valproate has no effect on PER levels **Other (partial list)**: PER decreases estrogen OCP levels	**Common**: CNS effects including dizziness, somnolence, fatigue, falls, vertigo, ataxia, headache, confusion; GI effects including nausea, weight gain, vomiting, abdominal pain; behavioral effects including irritability anxiety; weight gain; falls sometimes leading to serious head injuries **Serious but rare**: DRESS
Pregabalin (PGB) (Schedule V) Capsule, tablet CR, oral solution	**MOA**: Binds to presynaptic α2δ subunit of calcium channels	**Advantages**: Useful in patients with diabetic peripheral neuropathy, postherpetic neuralgia, fibromyalgia, neuropathic pain with spinal cord injury; minimal DDIs due to renal excretion	**Effect of PGB on ASMs**: No significant effects	**Common**: CNS effects including dizziness, somnolence, blurred vision, difficulty with concentration and attention; dry mouth; edema and weight gain
	Indication: Adjunctive therapy for focal onset seizures in patients ≥4 years of age	**Disadvantages**: Caution in preexisting cognitive disorders; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on PGB**: No significant effects	**Serious**: Potential for misuse when taken with opiates **Long term**: Weight gain
Third-Generation ASMs with FDA Approval for Specific Epilepsy Syndrome Indications				
Cannabidiol (CBD, Schedule V) Oral solution	**MOA**: Unknown, does not act on cannabinoid receptors	**Advantages**: Useful for refractory seizures in LGS and Dravet Syndrome	**Effect of CBD on ASMs**: CBD increases lamotrigine levels; CBD increase levels of clobazam active metabolite by 3x	**Common**: CNS effects including somnolence, fatigue, malaise, asthenia; sleep disorders including insomnia, poor quality sleep; GI effects including decreased appetite; diarrhea; transaminase elevations
	Indication: Monotherapy/adjunctive therapy for patients with LGS and Dravet Syndrome, ≥2 years of age	**Disadvantages**: Avoid in patients with hypersensitivity reactions to cannabis, THC; liver function and bilirubin monitoring before and at 1, 3, and 6 months of treatment specially if given with valproate; no adequate data in pregnant woman—may cause fetal harm	**Effect of ASMs on CBD**: CYP3A4 and CYP2C19 inhibitors will increase CBD levels; CYP3A4 and CYP2C19 inducers will decrease CBD levels	**Serious but rare**: Hepatotoxicity; hypoxia; respiratory failure
Clobazam (CLB, Schedule IV)	**MOA**: Binds $GABA_A$ receptor and potentiates	**Advantages**: none	**Effect of CLB on ASMs**: CLB is inhibitor of	**BOXED WARNING**: Concomitant use with

Tablet, oral suspension	GABA by modulating chloride conductance		CYP2C9 and inducer of CYP3A4; CLB may affect levels of CYP2C9, CYP3A4 substrates	opioids increases risk of death **Common**: CNS effects including somnolence, sedation, lethargy; pyrexia; constipation; drooling
	Indication: Adjunctive therapy for patients with LGS ≥2 years of age	**Disadvantages**: Monitor patients with history of substance use; use with other CNS depressant may produce additive CNS effects; may cause respiratory depression, coma, and death; no adequate data in pregnant patients—may cause fetal harm	**Effect of ASMs on CLB**: Carbamazepine, felbamate, phenobarbital, phenytoin, primidone may decrease CLB levels; cannabidiol, cenobamate, stiripentol increases CLB levels **Other (partial list)**: CLB decreases estrogen OCP levels	**Rare but serious**: Rash (SJS, TEN); anemia; liver enzyme elevations; respiratory depression
Fenfluramine (FEN, Schedule IV) Oral solution	**MOA**: Increases extracellular serotonin through actions on serotonin transporter protein, agonist at serotonin 5HT$_2$ receptors	**Advantages**: Useful for refractory seizures in Dravet Syndrome	**Effect of FEN on ASMs**: No significant effects **Effect of ASMs on FEN**: CYP1A2, 2B6 inducers will decrease FEN; stiripentol + clobazam will increase FEN concentrations (max daily dose of FEN is reduced to 17mg); cyproheptadine and potent 5-HT serotonin receptor binding agents may decrease efficacy of FEN **Other (partial list)**: Rifampin will decrease FEN, strong CYP1A2 and CYP2B6 inducers will decrease FEN	**BOXED WARNING**: Risk of valvular heart disease and pulmonary arterial hypertension; echocardiograms required before, during, and after treatment **Common**: GI effects like decreased appetite/weight, vomiting; diarrhea, constipation; CNS effects like somnolence, sedation, lethargy; fatigue, malaise, asthenia; ataxia, balance disorder, gait disturbance; blood pressure increase; salivary effects like drooling, hypersecretion; pyrexia; falls; status epilepticus; abnormal echocardiogram **Rare but serious**: increased blood pressure including hypertensive crisis; risk of valvular disease and pulmonary arterial hypertension; mydriasis precipitating acute angle closure glaucoma
	Indication: Treatment of seizures associated with Dravet Syndrome in patients ≥2 of age	**Disadvantages**: Contraindicated within 13 days of MAO inhibitors due to risk of serotonin syndrome; may increase blood pressure; not recommended in severe hepatic or renal impairment; available only through FINETPLA REMS; no adequate data in pregnancy—may cause fetal harm		
Rufinamide	**MOA**: Selectively	**Advantages**: useful for refractory seizures	**Effect of RFN on**	**Common**: CNS effects

(RFN) Tablet, oral suspension	enhances fast inactivation of voltage-gated sodium channels	in LGS	**ASMs**: RFN is weak inhibitor of CYP2E1 and weak inducer of CYP3A4; RFN modestly decreases levels of carbamazepine, lamotrigine; RFN increases levels of phenobarbital, phenytoin	including somnolence, fatigue, coordination abnormalities, dizziness, gait disturbances, ataxia; GI effects including nausea **Rare but serious**: DRESS; rash (SJS); status epilepticus; leukopenia; QT interval shortening
	Indication: Adjunctive therapy for patients with LGS ≥1 year of age	**Disadvantages**: Contraindicated in severe liver impairment or in familial short QT syndrome; use caution with other drugs that shorten QT interval; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on RFN**: Carbamazepine, phenobarbital, phenytoin decrease RFN levels by 19%-46%; valproate increases RFN levels up to 70%	
			Other (partial list): RFN decreases estrogen OCP levels	
Stiripentol (STP), capsule	**MOA**: Possibly acts on $GABA_A$ receptor and may also inhibit CYP450 to increase blood levels of clobazam and its active metabolite	**Advantages**: Useful for refractory seizures in Dravet Syndrome	**Effect of STP on ASMs**: STP is inhibitor and inducer of CYP1A2, 2B6, 3A4 and possible inhibitor of CYP2C8, 2C19, P-gp transporter, BCRP transporter; STP increases clobazam concentration 2-fold and clobazam active metabolite 5-fold (must decrease clobazam dosage when used together)	**Common**: Somnolence, decreased appetite/weight, agitation, ataxia, hypotonia, nausea, tremor, dysarthria, insomnia
	Indication: Adjunctive therapy with clobazam for seizure associated with Dravet Syndrome in patients ≥2 (no evidence for monotherapy)	**Disadvantages**: Must be used as adjunctive therapy with clobazam; hematologic testing is required prior to first dose and q6months after due to risk of neutropenia and thrombocytopenia; powder formulation contains phenylalanine and is a risk in patients with phenylketonuria; not recommended in moderate or severe hepatic or renal impairment; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on STP**: STP is substrate of CYP1A2, CYP2C19, CYP3A4 and phenytoin, phenobarbital, carbamazepine may decrease stiripentol levels	**Rare but serious**: Neutropenia and thrombocytopenia; monitor
Vigabatrin (VGB)	**MOA**: Binds to and	**Advantages**: Useful in infantile spasms	**Effect of VGB on**	**BOXED WARNING**:

Tablet, powder packet	irreversibly inhibits GABA transaminase	for whom potential benefit outweighs risk of vision loss; renally cleared and has less DDIs than other ASMs	**ASMs**: VGB is inducer of CYP2C9; VGB decreases levels of phenytoin by 20%; VGB possibly increases levels of carbamazepine by 10%; VGB increases Cmax of clonazepam	Progressive and permanent bilateral peripheral visual loss including tunnel vision and decrease in visual acuity **Common**: CNS effects including fatigue, somnolence, nystagmus, tremor, blurred vision, memory impairment, abnormal coordination, confusion; weight gain; edema; peripheral neuropathy; laboratory abnormalities including decreases in ALT/AST in pediatric patients; aggression; infection including upper respiratory tract infection, bronchitis, ear infection, and acute otitis media constriction including tunnel vision; reduced visual acuity
	Indication: Adjunctive therapy for refractory focal onset seizures in patients ≥2 years of age (not indicated as first-line); monotherapy for infantile spasms in patients 1 month to 2 years of age	**Disadvantages**: Permanent vision loss in most patients after a certain duration of exposure requiring eye exams Q3 months; requires REMS program registration; no adequate data in pregnancy—may cause fetal harm	**Effect of ASMs on VGB**: carbamazepine, primidone, valproate have no effect on VGB **Other (partial list)**: unlikely to affect estrogen OCP levels	**Serious but rare**: Seizure exacerbation, particularly absence and myoclonic seizures in patients with generalized epilepsies; anemia; onset of vision loss is unpredictable and can occur after weeks, months, or years with risk increasing in a dose-related and life exposure–related manner; abnormal MRI signal changes in infants treated for infantile spasms strongly suggestive of intramyelinic edema in select brain areas

[a] All ASMs may increase the risk of suicidal thoughts or behavior and patients treated with an ASM should be monitored for the emergence or worsening of depression, suicidal thoughts or behavior, or any unusual changes in mood or behavior.

AMPA, A-Amino-3-Hydroxy-5-Methyl-4-Isoxazolepropionic Acid; ASM, antiseizure medication; AV, atrioventricular; BUN, blood urea nitrogen; C_{max}, maximum concentration; CNS, central nervous system; CR, controlled-release; CrCl, creatinine clearance; CYP, cytochrome p450 isoenzyme system; DDI, drug–drug interaction; DR, delayed-release; DRESS, drug rash with eosinophilia and systemic symptoms; EEG, electroencephalogram; FDA, Food and Drug Administration; ER, extended release; GABA, gamma-aminobutyric acid; GAT1, GABA transporter type 1; GI, gastrointestinal; GFR, glomerular filtration rate; HLA, human leukocyte antigen; IQ, intelligence quotient; IR, immediate release; IV, intravenous; LGS, Lennox–Gastaut syndrome; OCP, oral contraceptives; ODT, orally dissolving tablet; PTSD, posttraumatic stress disorder; SJS, Steven–Johnson syndrome; TEN, toxic epidermal necrolysis; TBI, traumatic brain injury; TC, tonic–clonic; UGT, UDP-glucuronosyltransferase; XR, extended-release.

Data from References 17–20,23,36–56,69–72.

The evidence for ASM long-term efficacy in new-onset or untreated epilepsy was reviewed by the ILAE in 2013 and the AAN in 2018. Based on evidence, ASMs were labeled as "established as efficacious," "probably efficacious," "possibly efficacious," or "potentially efficacious" for new-onset epilepsy of various types including focal epilepsies in children, adults, and older individuals; focal, generalized, or unclassified epilepsy with tonic–clonic seizures in children and adults; and epilepsy syndromes like CAE, JME, and benign epilepsy with centro-temporal spikes (BECT).[27] Additionally, the ILAE and AAN identified limited evidence that some ASMs may possibly precipitate or aggravate certain seizure types, and, therefore, it is suggested that they should be used with caution in those patients (eg, carbamazepine and phenytoin in generalized onset tonic–clonic seizure types or carbamazepine, gabapentin, oxcarbazepine, phenytoin, tiagabine, and vigabatrin among others in patients with CAE or JME).[27] Despite the availability of ILAE and AAN recommendations summarizing ASM efficacy, based on the best available evidence in both new-onset and refractory epilepsy, there continues to be limited evidence to definitively guide pharmacotherapy decisions for refractory epilepsy.[73,74] Therefore, after assessing the evidence for ASM efficacy for a particular epilepsy or seizure type, pharmacotherapy decisions are guided by patient-specific factors, tolerability, risk for medication adverse reactions, and medication interactions (Tables 75-1–75-4).

ASM Effectiveness

In general, ASM "efficacy" is a measure of the ability of an ASM to prevent seizures or reduce their frequency in "ideal" circumstances. In contrast, ASM "effectiveness" is a more pragmatic measure of ASM benefit in "real-world" clinical setting and takes into account tolerability and their adverse reaction profiles. While ASM "efficacy" is generally considered similar in focal-onset epilepsies, ASM "effectiveness" varies and may be dependent on individual patient characteristics. Therefore, knowledge of individual ASM adverse reactions is important in determining ASM effectiveness and plays a significant role in their selection and optimization.

Adverse medication reactions can be categorized into two categories, dose-related (eg, concentration dependent) and idiosyncratic. As ASMs are often used life-long, adverse reactions associated with chronic long-term use and related to overall cumulative exposure should also be recognized. A general approach to understanding these different categories of ASM adverse reactions is reviewed in the following sections. For specific adverse reactions associated with each individual ASM, please refer to Table 75-2.

ASM Concentration-Dependent Adverse Medication Reactions

All ASMs have some common dose-related adverse reactions that they share as a class, as well as their own unique dose-related profile, often related to medication mechanism of action. As all ASMs act on the CNS to exert antiseizure effects, they all commonly cause dose-related CNS adverse reactions including sedation, dizziness, blurred or double vision, difficulty with concentration, ataxia, and impaired cognition which is of particular concern. Barbiturates and sodium channel inhibitors in particular cause more sedation and cognitive impairment than other commonly used ASMs (although in children, barbiturates may paradoxically cause hyperactivity). While newer agents have been associated with a lower incidence of CNS adverse effects, topiramate, in particular, is known to cause substantial cognitive impairment.[75]

Concentration-dependent adverse reactions are common and troublesome but not usually life-threatening, as they can be avoided by titrating the dose upward very slowly in many cases or can be alleviated by decreasing the dose.[76] Although they are more likely to occur at higher doses and higher concentration ranges, it is important to note that patients dosed and maintained below or within "therapeutic concentration ranges" may still experience these reactions.[77] Patients who change from polytherapy with multiple agents to dual therapy or monotherapy may also demonstrate improvement in CNS adverse reactions, especially if principles of rational polytherapy are used.

ASM Idiosyncratic Adverse Medication Reactions

More uncommon are idiosyncratic adverse reactions, which are generally related to chemical characteristics of the ASM and individual patient susceptibility, rather than the ASM's pharmacology. While most idiosyncratic reactions are mild, they can be serious, potentially life threatening, and can affect virtually any organ, although the skin, liver, and blood cells are most commonly affected. The most widely recognized idiosyncratic reactions associated with ASMs are rashes, which are more common with particular ASMs (eg, carbamazepine, phenytoin, phenobarbital, and lamotrigine) but may occur with any. While these rashes are often mild, some can progress to severe life-threatening rashes including Steven–Johnsons syndrome (SJS) or toxic epidermal necrolysis (TEN). Hepatitis or blood dyscrasias have also occurred with many ASMs and can progress to acute hepatic failure or fatal aplastic anemia such as those rare cases reported with felbamate. Additionally, ASM treatment itself may sometimes worsen seizures as a paradoxical toxic effect of the medication.[75,76]

A warning on suicidal behavior and ideation also accompanies all ASMs. This is based on pooled analyses of almost 200 placebo-controlled trials of 11 different ASMs showing that patients randomized to an ASM had approximately twice the risk of suicidal thinking or behavior compared to patients randomized to placebo. While the estimated incidence of suicidal ideation was low, less than 0.5% of patients on ASMs, this was greater than the 0.24% of patients on placebo. While some believed that this risk is nonsignificant, responsible providers must carefully assess this risk when evaluating their patients for ASM therapy, especially as depression and anxiety are common comorbid conditions in epilepsy. Patients and caregivers should be informed that ASMs may increase the risk of suicidal thoughts and should be advised to be on the alert for any unusual changes in mood or behavior.[76]

Adverse ASM Reactions Associated with Chronic Therapy

Antiseizure medications are often used life-long and one adverse reaction of chronic ASM therapy is osteomalacia and osteoporosis.[78,79] The effects on bone can range from asymptomatic high-turnover disease with findings of normal bone mineral density, to markedly decreased bone mineral density sufficient to warrant the diagnosis of osteoporosis. It has been hypothesized that mechanistically certain ASMs, including phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate, and valproate, may interfere with vitamin D metabolism to cause this adverse reaction.[80] It is unknown whether other ASMs also cause osteomalacia and/or osteoporosis, but patients receiving chronic therapy should receive supplemental vitamin D and calcium, as well as bone mineral density testing if other risk factors for osteoporosis are present.

Antiseizure Medications

Of the ASMs available, their mechanisms of action fall into four broad categories: (1) modification of ionic conductance (eg, sodium channel inhibition, calcium channel inhibition); (2) enhancement of GABAergic (inhibitory) neurotransmission (eg, $GABA_A$-receptor agonism, inhibition of GABA metabolism/reuptake); (3) suppression of excitatory (usually glutamergic) excitatory neurotransmission (eg, inhibition of kainate/α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid [AMPA] receptor, inhibition of *N*-methyl D-aspartate [NMDA] receptor, and SV2A binding and modulation of excitatory neurotransmitter release); and lastly (4) other unique or unknown mechanisms.[69] While it is useful to know mechanism of action for rational therapy and polytherapy, it is easiest to organize the ASMs into three generations which are not determined by structure or mechanism of action but by the time period in which they were FDA approved. Each of the three generations of ASMs have specific characteristics that should be considered during selection of initial and subsequent ASM therapy. The following section is meant to highlight these major characteristics. Certain unique characteristics of specific medications within each class are also highlighted. For more specific information on pharmacokinetics, dosing, FDA-approved indication, preferred use in therapy, medication interactions, and adverse medication effects, see Tables 75-2–75-4. For additional detailed information on each ASM, the reader is referred to the individual FDA-approved ASM package inserts.

First-Generation ASMs

⑦ The first-generation ASMs, approved by the FDA from 1908 to 1978 are (1) carbamazepine, (2) clonazepam, (3) ethosuximide, (4) phenobarbital, (5) phenytoin (and its esterified prodrug fosphenytoin), (6) primidone, and (7) valproate. Valproate is available as valproic acid and divalproex, which is a specific formulation of valproate composed of sodium valproate and valproic acid in a 1:1 molar relationship. Within the gastrointestinal track, divalproex dissociates to valproate as the active form.[69] The ASMs within this class, while considered to be among the most efficacious in controlling seizures, have complex pharmacokinetics, multiple interactions, and an increased incidence of adverse reactions that, in general, make them more complicated to manage than either the second- or third-generation ASMs.

Mechanisms of Action

With the exception of ethosuximide, all the first-generation ASMs have mechanisms of action that act either to primarily promote GABAergic activity or to inhibit sodium channels. The GABAergic first-generation ASMs include the barbiturate phenobarbital, primidone which is a prodrug metabolized to phenobarbital, and the benzodiazepine clonazepam which is a full $GABA_A$-receptor agonist.[20,37,69] Pharmacologically, these GABAerigic ASMs bind to sites at the $GABA_A$ receptor as agonists, increasing chloride channel opening and promoting hyperpolarization, which results in cells that are less susceptible to electrical impuses.[20,37,69] In contrast, phenytoin and carbamazepine bind to voltage-gated sodium channels in their inactive form preventing repetitive and sustained firing of sodium-dependent action potentials and stabilizing the threshold against hyperexcitability.[18,19,69] Because they bind the inactive form of the sodium channel, these agents cause a voltage-dependent and use-dependent block, which may preferentially target hyperexcitable areas that fire frequently.[18,19,69] Lastly, ethosuximide has a unique mechanism of action within this class and inhibits t-type calcium channels in cells of the thalamus and the cortex, preventing the abnormal firing of these cells that occur in absence epilepsies.[38,69]

Pharmacokinetics

First-generation ASMs have complex pharmacokinetics, especially phenytoin, with 90% of total phenytoin being protein bound in individuals with normal protein status and 10% being unbound as free phenytoin. Only unbound free phenytoin is pharmacologically active.[19] Reference ranges for total and free phenytoin levels were created with this ratio in mind, with a total phenytoin level in the therapeutic range of 10 to 20 mg/L (mcg/mL; 40-79 µmol/L) corresponding to a pharmacologically active free phenytoin level of 1 to 2 mg/L (mcg/mL; 4-8 µmol/L). Both total phenytoin and free phenytoin levels are routinely used in practice to guide therapy and it is important to understand what phenytoin level is being used to accurately interpret the true level of pharmacologically active medication. In patients with low protein status (eg, hypoalbuminemia, end-stage renal disease, critically ill patients), total serum phenytoin levels in the 10 to 20 mg/L (mcg/mL; 40-79 µmol/L) range no longer correspond to an active free phenytoin level of 1 to 2 mg/L (mcg/mL; 4-8 µmol/L) and does not reflect the true level of pharmacologically active phenytoin.[81] Monitoring of free phenytoin levels better reflect the true therapeutic levels in patients with hypoalbuminemia. However, free phenytoin levels, while commonly ordered, are not rapidly available through many laboratories (eg, results may take days to weeks). Valproate is also extensively bound to albumin, and due to saturable binding, the valproate free fraction will increase as the total serum concentration increases.[39] Similar to phenytoin therapeutic monitoring, the total valproate levels may not represent the amount of free medication available to exert a pharmacologic effect. However, free valproate levels are not commonly ordered, and only total valproate levels are generally available. Therefore, it is also important to know the patient's serum albumin level and protein status to aid in interpretation of total phenytoin and valproate serum levels.[39,81] This is especially true with phenytoin as various correction equations can be used to aid in interpreting total serum phenytoin levels in patients with low protein status, including the Winter–Tozer equation.[81] Valproate levels are not routinely corrected for low protein status in clinical practice, although it is still important to be aware of its possible effect. Carbamazepine, ethosuximide, and phenobarbital are also highly protein bound, but this has less of a clinically meaningful impact in practice.[18,37,38]

Phenytoin is metabolized in the liver by CYP450 enzymes and displays Michaelis–Menten pharmacokinetics.[36] At daily doses ≤ 300 mg, phenytoin's metabolism is generally linear in most patients. However, at doses ≥ 300 mg daily, it may saturate its metabolizing enzymes and a small change in dose can result in a disproportionally large increase in serum concentrations, potentially leading to toxicity.[19,36] This can also occur at low serum concentrations in some patients. Therefore, at phenytoin doses ≥ 300 mg, it is recommended to increase by 30-mg increments instead of 100-mg increments.

Carbamazepine, ethosuximide, phenobarbital, and valproate are also hepatically metabolized by CYP450 enzymes but in general display linear pharmacokinetics at clinically relevant doses.[18,37-39] An exception to this is ethosuximide which displays some evidence of nonlinear kinetics at higher concentrations.[38] Carbamazepine is a particularly strong inducer of CYP metabolism and induces its own metabolism in a process known as autoinduction, where its half-life starts decreasing 3 to 5 days after therapy initiation with autoinduction being complete within 21 to 28 days.[18,36] Importantly, the reversal of autoinduction is rapid upon carbamazepine discontinuation.

Carbamazepine, ethosuximide, phenobarbital, phenytoin, and valproate all have narrow therapeutic ranges and require monitoring of serum concentrations (see Table 75-3 for target therapeutic ranges of specific ASMs and section "Evaluation of Therapeutic Outcomes" for role of serum concentration monitoring).[36]

Medication Interactions

As all of the first-generation ASMs undergo CYP450 hepatic metabolism, they also have significant interactions. In particular, carbamazepine, phenobarbital, and phenytoin are substrates and inducers of many CYP enzymes. As such, they will affect each other's metabolism if used in combination and may result in decreased levels of one or the other medication. They also affect metabolism of all other ASMs and medications that go through similar CYP450 pathways (Table 75-4) and vice versa.[18,19,36,37]

Enzyme-inducing ASMs may also induce uridine 5′-diphospho-glucuronosyltransferase (UGT) metabolism and have significant interactions with medications that undergo UGT metabolism, like lamotrigine, a second-generation ASM that undergoes UGT1A4 metabolism.[18,19,36,37]

Valproate on the other hand is an inhibitor of CYP450 and UGT metabolism and inhibits the metabolism of the first-generation ASMs as well as other ASMs and medications that go through similar CYP450 and UGT pathways. In particular, valproate decreases the clearance of phenobarbital and lamotrigine by 30% to 50% and can lead to phenobarbital and lamotrigine toxicity.[36,39]

First-generation enzyme-inducing ASMs may cause increased clearance of oral contraceptives (OCs) compromising their efficacy. The enzyme inhibitor, valproate, does not cause OC failure but OCs may cause increased valproate metabolism and subsequent increased risk in seizures. Therefore, in a patient of child bearing age with epilepsy, education around these interactions is a must.[18,19,37,39]

Adverse Medication Reactions

The first-generation ASMs are, in general, associated with a higher incidence of dose-related and idiosyncratic adverse reactions including neurotoxic effects, hepatotoxicity, and SJS/TEN. There are also a number of unique adverse effects associated with first-generation ASMs that are of particular note such as hyponatremia with carbamazepine, hyperactivity with phenobarbital in children, and gingival hyperplasia and osteoporosis with chronic use of phenytoin.[18,40,49] Valproate especially has a number of unique adverse effects including concentration-dependent thrombocytopenia at serum levels above 100 mg/L (mcg/mL; 693 μmol/L), hyperammonemia related to carnitine deficiency that may or may not lead to encephalopathy, idiosyncratic pancreatitis, and well-known teratogenicity.[39,82] Adverse effects of first-generation ASMs are listed in Table 75-2.

Advantages and Disadvantages

First-generation ASMs are very efficacious in epilepsy. Valproate, in particular, is considered a broad-spectrum ASM and is useful in both focal-onset and generalized-onset seizures as well as various epilepsy syndromes.[27,73,74] Phenobarbital has been in use for the longest period of time and is readily available worldwide. Carbamazepine and phenytoin are very efficacious in focal-onset seizures and have known efficacy in controlling tonic–clonic seizures but may exacerbate other generalized seizures and should be used with caution in generalized-onset epilepsy, especially generalized atypical absence.[18,19,27,73,74] Valproate and carbamazepine are also useful in multiple other comorbid conditions including migraine and bipolar disorder.[18,39] Despite their known advantages, however, first-generation ASMs should generally be considered after second-generation ASMs have failed, due to the greater tolerability, fewer medication interactions, and generic availability of the second-generation ASMs. The exception to this rule is ethosuximide, which is the medication of first choice for treatment of absence seizures but has limited use in other epilepsies.[36,83]

Second-Generation ASMs

The second-generation ASMs were developed with knowledge regarding the limitations of the first-generation ASMs and were FDA approved from 1993 to 2000. Included in this class are (1) felbamate, (2) gabapentin, (3) lamotrigine, (4) levetiracetam, (5) oxcarbazepine, (6) tiagabine, (7) topiramate, and (8) zonisamide. In general, these medications are considered to have similar efficacy in controlling seizures as first-generation ASMs, have relatively simple pharmacokinetics with fewer interactions, and have an overall lower incidence of adverse effects.

Mechanisms of Action

⑧ The second-generation ASMs have mechanisms of action that include enhancement of GABAergic activity (eg, tiagabine) and sodium channel inhibition (eg, lamotrigine, oxcarbazepine, zonisamide) but also expand beyond that.[69] Notably, ASMs with novel mechanisms of action that were introduced within this generation include felbamate that modulates excitatory neurotransmission via inhibition of the *N*-methyl D-aspartate (NMDA) glutamate receptor, topiramate that inhibits the kainate/α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamate receptor,[40,50] and levetiracetam that modulates excitatory neurotransmission through modulation of presynaptic neurotransmitter release via inhibition of SV2A protein, considered the master regulator molecule of neurotransmitter release.[49,69] For the other medications in this class, their therapeutic effects are seen through novel mechanisms that have not been fully elucidated (eg, gabapentin that binds to presynaptic $\alpha^2\delta$ subunit of calcium channels, possibly resulting in decreased release of the excitatory neurotransmitters glutamate, noradrenaline, substance P, and calcitonin gene-related peptide).[41] Furthermore, topiramate and zonisamide are also carbonic anhydrase inhibitors, although whether or not this impacts antiseizure activity is unknown.[42,50] Additionally, during this time period, a second-generation structurally related derivative of carbamazepine, oxcarbazepine, was also introduced that exhibits a similar mechanism of action, but with an improved pharmacokinetic and adverse reaction profile.[43]

Pharmacokinetics

The second-generation ASMs also have pharmacokinetics that are less complex than first-generation ASMs. In general, they are not significantly protein bound and are well absorbed with good bioavailability, although of note, gabapentin relies on the L-amino acid carrier protein in the gut and the CNS to be actively transported across those membranes. As binding is saturable, this causes a dose-dependent bioavailability, with decreasing bioavailability with increasing dose, as the transporter is believed to be saturated at doses ≤ 1,200 mg per single dose.[41,84]

Unlike the first-generation ASMs which are all hepatically metabolized, two second-generation ASMs, gabapentin and levetiracetam, are primarily renally eliminated and dosage adjustments may be necessary in patients with significantly impaired renal function.[41,49] Additionally, topiramate is approximately 60% renally eliminated and should be dose adjusted in patients with renal impairment, although topiramate also undergoes CYP3A4 metabolism.[50] As for the remaining second-generation ASMs, felbamate, lamotrigine, oxcarbazepine, tiagabine, and zonisamide are all hepatically metabolized.[40,42-45] In contrast to carbamazepine, oxcarbazepine does not undergo autoinduction and also has an active metabolite (a monohydroxy derivative [MHD], 10-OH-carbazepine) that is inactivated by glucuronidation and eliminated by the kidneys. As such, oxcarbazepine may also require dosage reduction with significant renal impairment.[43]

Medication Interactions

Since gabapentin and levetiracetam do not undergo any appreciable hepatic metabolism, they display minimal medication interactions.[41,49] Felbamate, oxcarbazepine, tiagabine, zonisamide, and topiramate at higher doses are all hepatically metabolized and while there are some pharmacokinetic effects on the CYP450 pathways,[40,42,43,45,50] these effects are generally much less significant than those of the first-generation ASMs. Specifically, felbamate may induce or inhibit the metabolism of first-generation ASMs (or vice versa).[36,40] Oxcarbazepine inhibits CYP2C19 and induces CYP3A4/5, therefore, causing interactions with first-generation ASMs metabolized by these pathways, although to a lesser extent than its precursor carbamazepine. Additionally, oxcarbazepine may also reduce lamotrigine levels through a suggested induction of UGT enzymes, again to a lesser extent than its precursor carbamazepine.[36,43] Similarly topiramate is a weak inhibitor of CYP2C19 and an inducer of CYP3A4, therefore interacting with the first-generation ASMs as well as other medications that are metabolized by these pathways.[36,50]

Of the second-generation ASMs, lamotrigine has the most substantial interactions, which in some cases can be rather significant. Given valproate's enzyme-inhibiting properties, valproate can substantially inhibit the metabolism of lamotrigine, while carbamazepine, phenobarbital, phenytoin can substantially increase the metabolism of lamotrigine due to enzyme induction. As such, detailed dose and titration recommendations are available in the situation for when lamotrigine is used in combination with these ASMs. It is important to follow dose titration recommendations for lamotrigine carefully, as too rapid dose titrations increase the risk for rash including SJS. Of note, lamotrigine itself does not inhibit liver enzymes and, therefore, has a low potential for pharmacokinetic interactions with other medications.[36,44]

Oxcarbazepine and topiramate both can interact with ethinyl estradiol and cause contraceptive failure, although topiramate doses ≤ 200 mg/day are unlikely to alter oral contraceptive pharmacokinetics.[43,50] The potential of lamotrigine to affect OC metabolism is minimal, but OCs can affect lamotrigine metabolism[44] as concomitant OCs lead to induction of lamotrigine glucuronidation by ethinyl estradiol. Once the OCs are withdrawn, significant increases in lamotrigine levels can be seen, including during the week of hormone withdrawal as part of various cyclic oral contraceptive treatments.[85]

In contrast to the first-generation ASMs, the second-generation ASMs have wide therapeutic ranges. While serum levels of second-generation ASMs are available through most laboratories, they are not routinely monitored, and levels may take many weeks to come back (see Table 75-3 for target therapeutic ranges of specific ASMs). One may monitor plasma levels of oxcarbazepine's active metabolite (MHD), which is more clinically significant than measuring oxcarbazepine levels directly. The therapeutic range for MHD is between 15 and 35 mcg/mL (mg/L; 59 to 138 μmol/L).[36]

Adverse Medication Reactions

The second-generation ASMs are associated with a lower incidence of dose-related CNS adverse reactions and are considered to be better tolerated than the first-generation ASMs. The exceptions are topiramate, which is associated with word-finding difficulties and cognitive slowing, and zonisamide which is a sodium channel inhibitor and associated with increased sedation and cognitive slowing. These neurotoxic effects are more common with rapid titration and high doses.[86,87]

Despite being better tolerated overall, there are a number of unique and severe adverse reactions associated with individual second-generation ASMs that must be considered when selecting therapy. The most severe of these is associated with felbamate which may potentially cause fatal idiosyncratic reactions including acute liver failure (1 in 10,000 patients), with reported onset between 68 and 354 days of therapy, and aplastic anemia (1 in 3,000 patients), with greater risk being seen in females, those with a history of cytopenia, prior ASM allergy or significant ASM toxicity, viral infection, and/or immunologic problems.[40] Tiagabine has been associated with new-onset seizures and status epilepticus.[45] Lamotrigine can cause rash, usually appearing after 3 to 4 weeks of therapy, and is typically generalized, erythematous, and morbilliform, but can progress to SJS. Rashes are more likely to occur if the patient has had a prior rash to another ASM[88] and risk factors for more serious rashes include concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used. When dosed appropriately, the incidence of rash is similar to that of carbamazepine and phenytoin. The incidence of lamotrigine rash is higher in children than in adults.[89]

Of more moderate severity, topiramate and zonisamide are uniquely associated with kidney stones which can occur in 1.5% to 4% of patients who should be encouraged to maintain adequate fluid intake for the prevention of this adverse effect. Topiramate and zonisamide can also cause metabolic acidosis especially in patients with renal disease, severe respiratory disorders, diarrhea, surgery, and in patients on the ketogenic diet.[42,50]

Levetiracetam is well-recognized for causing irritability in many patients, which may be lessened with dose reduction.[49] Similarly, in patients receiving gabapentin for pain, abrupt discontinuation is associated with a withdrawal reaction characterized by anxiety, insomnia, nausea, sweating, and increased pain.[41]

Oxcarbazepine generally causes fewer adverse effects than the first-generation carbamazepine, but may have a higher incidence of hyponatremia, reported in as high as 25% of patients.[83] This adverse event occurs more often in older adult patients and in patients receiving concomitant sodium-depleting medications such as diuretics and is not very common in children. The incidence of rash with oxcarbazepine is less compared to carbamazepine, although approximately 25% to 30% of patients who develop a rash with carbamazepine also experience a similar reaction with oxcarbazepine.[43]

Advantages and Disadvantages

As previously stated, the second-generation ASMs are considered to be similar in efficacy to first-generation ASMs, but with better tolerability and fewer medication interactions. Levetiracetam, in particular, is considered a useful broad-spectrum ASM with little, if any, CNS adverse effects besides irritability. It is routinely used as first-line monotherapy to treat focal-onset epilepsy and to a lesser extent myoclonic seizures of JME and primary generalized seizures, despite being only FDA approved as adjunctive treatment for those seizure types.[36,49] However, increasing recognition of the unusually high prevalence of irritability and impact on QOL is limiting more widespread use of levetiracetam.

Lamotrigine is also efficacious in many epilepsy types, and, besides rash, is generally well tolerated with minimal CNS adverse effects, especially in older adults patients who may experience less cognitive adverse effects with lamotrigine than with other ASMs.[90] However, its use is mainly limited by the need for slow titration to avoid rash (especially if the patient is on valproate) and it is not a good agent for patients who need to reach therapeutic ASM levels quickly.[44] Both lamotrigine and oxcarbazepine may be a good ASM for patients with comorbid bipolar disorder, with oxcarbazepine not requiring very slow dose titration.[36,43,44] (See Chapter 89 for more information on the role of these ASMs for bipolar disorder.)

Topiramate and zonisamide are efficacious agents but due to their effects on cognition are sometimes considered after other ASMs. Topiramate additionally requires a very slow titration due to its CNS adverse reactions, further limiting its use. On the other hand, topiramate is usually considered earlier in therapy for those patients with epilepsy who also have comorbid migraines or those who have a wish to lose weight as it has some efficacy in this regard. Similarly, zonisamide is considered earlier in therapy for those patients who have issues with medication adherence as it is dosed once daily and has one of the longest half-lives of all the ASMs.[36,42,50]

Gabapentin is oftentimes considered a poorly efficacious ASM that may even exacerbate generalized-onset seizures and should be avoided in generalized-onset epilepsies.[27,73,74] However, it is well tolerated and widely used as adjunctive therapy in focal-onset epilepsy mostly for its benefit in comorbid conditions such as neuropathic pain and not necessarily for its efficacy in controlling seizures.[41] Tiagabine and felbamate have serious adverse reactions and are generally reserved for use only after failure of other ASMs, which is unfortunate as felbamate is broad spectrum (eg, can be used in focal-onset epilepsies and generalized-onset epilepsy syndromes like Lennox–Gastaut syndrome [LGS]) and is an effective ASM.[40] Furthermore, because of the risk of fatal aplastic anemia and liver failure, the use of felbamate requires signed written consent.[40]

Third-Generation ASMs

The third-generation ASMs were FDA approved from 2004 to 2020 and agents in this generation can be further subcategorized into those that are approved for typical seizure indications and ASMs that are approved for specific epilepsy syndromes. The third-generation ASMs approved for typical seizure indications include (1) brivaracetam, (2) cenobamate, (3) eslicarbazepine, (4) lacosamide, (5) perampanel, and (7) pregabalin. The ASMs that are approved for specific epilepsy syndromes include (1) cannabidiol for LGS and Dravet Syndrome, (2) clobazam for LGS, (3) rufinamide for LGS, (4) stiripentol for Dravet Syndrome and (5) vigabatrin for focal onset seizures as well as infantile spasms. (Note, topiramate, a second-generation ASM is also approved for LGS as well as focal onset or primary generalized seizures.) While many of the ASMs were approved for very specific indications only, they are often used off-label in refractory epilepsy after failure of other first-line ASMs.

Mechanisms of Action

Similar to the first-generation ASMs, many of the medications within this classification pharmacologically exert their effects through sodium channel inhibition and GABAergic mechanisms, as these continue to be proven to be efficacious in preventing seizures. Of the third-generation ASMs noted above, eslicarbazepine, lacosamide, and rufinamide are third-generation sodium channel inhibitors.[46,53,56] Eslicarbazepine is a derivative of carbamazepine that has a 5- to 15-fold lower affinity for the resting state of sodium channels than that of carbamazepine or oxcarbazepine, leading to a selectivity for neurons that are firing (typically seen in epilepsy).[46,69] Eslicarbazepine is postulated to inhibit sodium channels, through enhancement of slow inactivation, similar to lacosamide, another third-generation sodium channel inhibitor. Rufinamide, on the other hand, prolongs the inactivation phase of sodium channels similar to phenytoin and carbamazepine.[53,56,69]

Third-generation GABAergic ASMs also include vigabatrin, clobazam, and stiripentol. Vigabatrin is an amino acid that is a structural analog of GABA and is a selective, irreversible inhibitor of GABA-transaminase, the enzyme that degrades GABA.[23] Clobazam is a 1, 5-chlorinated benzodiazepine derivative (structurally different from the 1,4 benzodiazepine clonazepam) that binds the $GABA_A$ receptor at the benzodiazepine site as an agonist and enhances inhibitory chloride ion transmission promoting hyperpolarization of the neuron. However, it demonstrates lower affinity for the $GABA_A$ subunits that facilitate sedation, thereby reducing the incidence of this particular adverse effect.[52] Additionally, unlike traditional benzodiazepines which are nonselective full receptor agonists, clobazam is believed to be only a partial agonist.[52,69] Stirpipentol is believed to possibly act on $GABA_A$ receptors and may also inhibit CYP450 enzymes to increase blood levels of clobazam and its active metabolite.[70] Cenobate is one of the newest ASMs and combines the two most common mechanisms of ASMs as it is believed to inhibit volgatge-gated sodium channels as well as being an allosteric modulator of the $GABA_A$ ion channel.[71]

In addition to these, two other derivatives of second-generation ASMs have also been introduced. The first agent is pregabalin, a derivative of gabapentin which pharmacologically works in a similar fashion by binding to presynaptic $\alpha^2\delta$ subunit of calcium channels.[55] The second agent is brivaracetam, a more selective derivative of levetiracetam that has a 15- to 30-fold higher affinity for SV2A, and binds SV2A to modulate neurotransmitter release and glutamergic transmission.[51,69]

Three new third-generation ASMs with novel mechanisms of action have also been introduced. Perampanel is a highly selective noncompetitive AMPA-type glutamate receptor antagonist,[54] and cannabadiol is purified derivative of cannabis whose exact antiseizure mechanism is unknown.[47] Fenfluramine's exact antiseizure mechanism is also unknown but it is known to increase extracellular serotonin through actions on serotonin transporter protein, and is an agonist at serotonin 5HT receptors and has efficacy in Dravet Syndrome.[72]

Pharmacokinetics

The third-generation ASMs have variable pharmacokinetic profiles which are unique to the individual agent and while some have simple pharmacokinetics, others have more complex pharmacokinetics almost similar to that of the first-generation ASMs.

Pregabalin and vigabatrin are the third-generation ASMs with the simple pharmacokinetics (ie, good absorption, low protein binding, uncomplicated metabolism, linear elimination kinetics) and are the only two in this generation that are renally cleared.[23,36,55] Rufinamide, while hepatically metabolized, also displays simple pharmacokinetics, undergoing biotransformation via a carboxylesterase-mediated hydrolysis with no involvement of the CYP450 and UGT system.[36,56] Eslicarbazepine, despite being a prodrug that requires hydrolytic first-pass metabolism in the liver to form its active metabolite S-licarbazepine, also has relatively simple pharmacokinetics. After first-pass, eslicarbazepine is subsequently glucuronidated and renally excreted, requiring dosage adjustment in renal impairment but surprisingly not requiring adjustment in hepatic impairment.[36,46] Lacosamide is 40% renally eliminated and 60% hepatically metabolized by CYP3A4, CYP2C9, and CYP2C19, requiring dose adjustment in renal and hepatic impairment, but otherwise displays relatively simple pharmacokinetics.[36,53]

The third-generation agents with more complex pharmacokinetic profiles are brivaracetam, clobazam, and perampanel. Brivaracetam is metabolized by CYP2C19, and CYP2C19 poor and fast metabolizers may display altered brivaracetam pharmacokinetics. Brivaracetam dosage adjustment is required in all stages of hepatic impairment.[36,51] Clobazam is metabolized in the liver by CYP3A4 and CYP2C19 to a primary active metabolite *N*-desmethylclobazam which is then metabolized by CYP2C19. As such, its pharmacokinetics are also affected by CYP2C19 polymorphic variants and it also requires dosage adjustment in hepatic impairment.[36,52] Perampanel is highly protein bound (96%-96%) and eliminated primarily via CYP3A4 metabolism to an inactive metabolite with an elimination half-life of about 100 hours. Its use is not recommended in severe renal or hepatic impairment.[36,54]

Fenfluramine is complicated because it goes through hepatic metabolism by CYP1A2, CYP2B6, CYP2D6 with minor involvement of a few other CYPs to an active metabolite norfenfluramine which is then inactivated. Similarly stiripentol is also metabolized by CYP1A2, CYP2C19, and 3A4.[70,72] Of note, eslicarbazepine and perampanel are the two ASMs in this generation that have long half-lives and are dosed once-a-day. Monitoring of third-generation ASM serum concentrations is not routinely done and therapeutic ranges have not been clearly identified for some of these agents.[36]

Medication Interactions

As previously stated pregabalin does not undergo hepatic metabolism and, similar to its precursor gabapentin, has little to no interactions.[36,55] Vigabatrin, while not hepatically metabolized, is an inducer of CYP2C9 and has been noted to have slight effects on CYP2C9 substrates (eg, decreases phenytoin plasma levels by approximately 20% and possibly increases serum carbamazepine by 10%).[23,36]

Third-generation ASMs with fewer interactions are lacosamide, rufinamide, and fenfluramine. Lacosamide levels may be increased if used in combination with strong inhibitors of CYP3A4, CYP2C9, but most of these interactions are clinically insignificant.[36,53] Lacosamide is also a substrate of CYP2C19 and its blood levels can be modestly decreased (~15%-20%) by enzyme-inducing ASMs.[36,53] Rufinamide, a weak inhibitor of CYP2E1 and a weak inducer of CYP3A4 may modestly affect the clearance of carbamazepine, lamotrigine, phenobarbital, and phenytoin and vice versa.[36,56] Additionally, concurrent use of rufinamide and OCs may result in reduced OCs efficacy while lacosamide does not reduce OC levels.[53,56] In regards to fenfluramine, stiripentol and clobazam combination act upon fenfluramine to increase its levels and other potent serotonin receptor binding agents may decrease its efficacy. However, fenfluramine does not generally act upon other ASMs and therefore has fewer interactions.[72]

Third-generation ASMs with more significant interactions include brivaracetam, clobazam, eslicarbazepine, and perampanel. Brivaracetam is a CYP2C19 substrate, and carbamazepine, phenobarbital, and phenytoin decrease its levels. Brivaracetam in turn may increase levels of the carbamazepine-epoxide metabolite and phenytoin levels but does not interact with lamotrigine, levetiracetam, oxcarbazepine, topiramate, valproate, or OCs to a significant extent.[51] Clobazam is a CYP3A4 and CYP2C19 substrate and its levels may be affected by CYP3A4- and CYP2C19-inducing and -

inhibiting medications such as felbamate and the first-generation ASMs, respectively.[36,52] Additionally, clobazam inhibits CYP2D6 and may affect the metabolism of other medications that use this pathway as well as lowering the serum levels of some OCs due to its weak induction effect on CYP3A4.[52] Like carbamazepine, eslicarbazepine is affected by CYP2C19 inducers and can itself inhibit CYP2C19 and affect plasma concentration of medications metabolized by this enzyme. However, similar to oxcarbazepine, the effects of eslicarbazepine are less significant than carbamazepine. Eslicarbazepine can also induce CYP3A4 affecting medications that are metabolized by this isoenzyme and may also lower OC levels.[36,46] Stiripentol is an inducer and inhibitor of multiple CYP enzymes and may also possibly be an inhibitor of the P-glycoprotein (Pgp) and breast cancer resistance protein (BCRP) transporters.[70] Of the third-generation ASMs, perampanel has the most potential for interactions as its serum levels are decreased by enzyme-inducing ASMs, it displays modest enzyme-inducing properties of its own at the high end of its dose range (12 mg/day), and it may lower OC levels.[36,54]

Adverse Medication Reactions

Third-generation ASMs have adverse reactions which are unique to the individual ASM, with some having minimal adverse effects, while others are known for specific serious effects. As the third-generation agents are the most recently FDA-approved ASMs, we have the least long-term experience with their use clinically; therefore, long-term and rare adverse effects may emerge as we gain more experience with them in a large population.

Among this generation, brivaracetam, lacosamide, and pregabalin are generally well tolerated, although we have the least experience with brivaracetam. In general, lacosamide's primary adverse reactions are CNS; however, these occur at a lower incidence than other ASMs and are more common in patients receiving concomitant treatment with other sodium channel inhibitors. Additionally, lacosamide is also associated with a lengthening of the PR interval which is not clinically significant unless used in combination with another ASM that lengthens the PR interval.[53] Pregabalin has an adverse effect profile that is notable for sedation and weight gain.[55]

Similarly, clobazam also is not commonly associated with any serious adverse reactions beyond CNS effects, but as a benzodiazepine, abrupt discontinuation may cause a withdrawal syndrome which could include seizures, psychosis, hallucinations, behavioral disorder, tremor, anxiety, dysphoria, and insomnia.[52]

In contrast, eslicarbazepine, rufinamide, and perampanel have more serious adverse reactions. Eslicarbazepine as a sodium channel inhibitor is associated with CNS effects and hyponatremia, although the occurrence of hyponatremia with this agent is less common than with carbamazepine and oxcarbazepine.[46] Eslicarbazepine like its earlier counterparts may still be associated with rash including SJS and TEN, hepatotoxicity, and hematologic adverse reactions. As rufinamide is also a sodium channel inhibitor, it is also associated with increased CNS effects as well as some rare and serious adverse reactions including an increased incidence of seizures and precipitation of status epilepticus. Additionally, multiorgan hypersensitivity has occurred within 4 weeks of starting treatment with rufinamide in patients younger than 12 years of age.[56] Aggression is a major common adverse reaction with perampanel and there is a FDA-boxed warning pertaining to monitoring of psychiatric, behavioral, mood, or personality changes which may be life-threatening.[54] Cenobamate mostly has CNS adverse reactions but there is also a risk of drug reactions with eosinophilia and systemic symptoms (DRESS) with fast titration; therefore, the dosage should be increased no faster than every two weeks. Additionally cenobamate is associated with QT interval shortening and a rate of appendicitis which was higher than in the normal population. Stiripentol may cause neutropenia and thrombocytopenia which necessitates frequent monitoring of blood counts including prior to the first dose and every 6 months during and 6 months after discontinuing. Fenfluramine which was previously used as a weight-loss medication has known cardiac effects at higher doses and has a boxed warning regarding risk of valvular heart disease and pulmonary arterial hypertension, which requires echocardiograms before, during, and after treatment.[70-72]

Vigabatrin has the most serious adverse effects in this generation, as it may cause progressive, irreversible, bilateral concentric visual field constriction in a high percentage of patients. It may also reduce visual acuity in a dose-related and life exposure–related manner. Vigabatrin also may aggravate seizures, particularly absence and myoclonic seizures in patients with generalized epilepsies, and patients with history of depression, psychosis, or behavioral disturbances may be at greater risk to develop psychiatric effects with vigabatrin use.[23,91] Furthermore, in up to 11% of patients (up to age 3 years) treated with high doses of this medication for infantile spasms, MRI findings have been strongly suggestive of intramyelinic edema in select brain areas. While these findings appear to be reversible, their significance is unclear.[23,91]

Advantages and Disadvantages

Cannabadiol, fenfluramine, rufinamide, stiripentol, and vigabatrin have all been approved for specific epilepsy syndromes (Dravet syndrome and LGS, LGS, and infantile spasms, respectively) and in general should be considered for those indications.[23,47,56]

9 In regards to focal-onset epilepsies, third-generation ASMs have been used in clinical practice for the treatment of these epilepsies and probably have similar efficacy to the first- or second-generation ASMs. However, most third generations are not available in generic form now (except for pregabalin) and are less cost-effective than other ASMs. Therefore, third-generation ASMs should be reserved for use after failure of other agents.

Of the third-generation ASMs, lacosamide has become an ASM of choice among many providers, due to its ease of use, including the availability of intravenous loading and lack of medication interactions. However, there is no strong evidence to support this practice and lacosamide is only available as a brand product. Therefore, due to its cost, lacosamide should be reserved as second-line or third-line therapy after failure of other equally efficacious, less expensive ASMs.

Among the third-generation ASMs, clobazam may have the broadest use, as clobazam is believed to be efficacious in a wide variety of epilepsies including focal-onset and primary generalized epilepsies (despite having FDA approval only for LGS seizures) and perampanel is broadly approved for focal-onset seizure with or without secondary generalization as well as for primary GTC seizures.[52,54] Perampanel use, however, is somewhat limited by the appearance of aggression in some patients.[54]

Lastly, all ASMs in this generation except for eslicarbazepine, rufinamide, and vigabatrin are controlled substances making prescribing and access more difficult for these ASMs.[46,47,51-56] While vigabatrin is not a controlled substance, access is still restricted as all providers must be certified in the Vigabatrin Risk Evaluation and Mitigation Strategy (REMS) Program in order to prescribe it.[23]

Therapeutic Considerations in Older Adults and Young

The most important aspect of ASM therapy is tailoring the choice of medication to the individual patient using knowledge of an individual ASM's pharmacodynamic and pharmacokinetic profile and its known advantages and disadvantages combined with knowledge of patient-specific factors including seizure type(s), age, sex, concomitant medical problems (including hepatic function, renal function), and interactions with concurrent medications.

In general, older adults are more often on many different medications which may contribute to increased sensitivity to neurocognitive effects. Additionally, this population may be more prone to the increased possibility of interactions with ASMs that affect the CYP450 system (eg, carbamazepine, phenytoin, and valproate); therefore, a thorough review of all medications is necessary prior to starting or modifying treatment. Hypoalbuminemia is also common in older adults, and highly albumin-bound ASMs (eg, phenytoin and valproate) should be closely monitored.[77] As patients age, they can also experience changes in body mass, such as an increase in fat to lean body mass or decrease in body water, which can affect volume of distribution and elimination half-life.[77] In addition, the older adults may have compromised renal or hepatic function that require ASM dosage adjustment.[77] Lamotrigine is often considered the medication of choice in older adults with focal-onset seizures, as results from a Department of Veterans Affairs cooperative trial found that it had equal efficacy to carbamazepine and gabapentin and was better tolerated than carbamazepine.[90]

For neonates and infants, an increase in the total body water to fat ratio and a decrease in serum albumin and α-acid glycoprotein can result in volume of distribution changes that affect ASM elimination half-life. Additionally, infants up to the age of 3 years have decreased renal elimination of ASMs, with neonates being the most affected. Hepatic activity is also reduced in neonates and infants, but by age 2 to 3 years, hepatic activity becomes more robust than that seen in adults. Therefore, whereas neonates and infants require lower doses of ASMs, children require higher doses than that seen in adults. Therapeutic medication monitoring becomes especially important in the young, even though the definitions of therapeutic blood levels are less certain in these patients than in adults.[77]

Therapeutic Considerations in Females (and Males)

Estrogen and progesterone are among the many hormones that can influence brain electrical excitability, as estrogen has a slight proconvulsant effect, whereas progesterone exerts a mild antiseizure effect.[15] In some individuals, vulnerability to seizures is highest just before and during the menstrual flow (catamenial seizures) and at the time of ovulation, which is believed to be due to a slight increase in estrogen relative to progesterone, or due to progesterone withdrawal and changes in the estrogen-to-progesterone ratio.[15] The risk of catamenial seizures is estimated be anywhere from 10% to

70% in females with epilepsy.[15] In these individuals, conventional ASMs should be used as primary agents, but intermittent supplementation with higher dose of ASM or benzodiazepines should be considered. Acetazolamide has also been used during catamenial periods, but with variable and limited success, and hormonal therapy with progestational agents, particularly cyclic natural progesterone therapy, may be effective in certain subsets of patients.[92]

At menopause, seizures often improve in frequency, particularly in individuals with a catamenial seizure pattern. However, for patients requiring hormone replacement therapy, it has been reported that conjugated equine estrogens plus 2.5 mg of medroxyprogesterone acetate may increase the frequency of epileptic seizures. Therefore, a hormone replacement therapy that consists of just a single estrogenic compound, such as 17-β-estradiol, along with a natural progesterone, may be recommended for individuals with disruptive menopausal symptoms.[93]

Antiseizure medications may also have an effect on endogenous and exogenous hormones. As previously stated, enzyme-inducing ASMs increase the metabolism of estrogen, progesterone, and testosterone and increase production of sex hormone-binding globulin, leading to decreases in the free fraction of these hormones endogenously. These alterations lead to disturbances in the regulation of the hypothalamic–pituitary–adrenal axis and contribute to reproductive endocrine disorders including menstrual irregularity, infertility, sexual dysfunction, and in some patients polycystic ovary syndrome (PCOS).[94] Valproate, in particular, may affect sex hormone concentrations causing hyperandrogenism and polycystic changes, especially in individuals who have gained weight or those who start valproic acid prior to age 20.[94] Exogenously, enzyme-inducing ASMs can cause treatment failures in individuals taking OCs, as discussed in the prior sections, due to increased metabolism of ethinyl estradiol and progestin. Medroxyprogesterone depot injections and hormone-releasing intrauterine systems, on the other hand, are not similarly affected by ASMs, and it is unclear if there is an effect of ASMs on the transdermal contraceptive patch or the emergency contraceptive pill. A supplemental or alternative form of birth control (eg, IUD) is advised if breakthrough bleeding occurs in individuals taking certain types of ASMs (eg, enzyme-inducing ASMs) and OCs, and it has been suggested that they use twice the normal dose of emergency contraception.[95]

Data suggests that males with epilepsy have reduced fertility, and that carbamazepine, oxcarbazepine, and valproic acid are associated with sperm abnormalities. In addition, valproic acid seems to cause testicular atrophy resulting in reduced testosterone volume, whereas levetiracetam slightly increases serum testosterone. Various ASMs have also been anecdotally reported to affect libido and sexual function in both males and females.[95]

Therapeutic Considerations for Pregnancy and Lactation

Pregnancy and epilepsy is a particularly complex topic. The goal of treatment in pregnant patients with epilepsy is to achieve the best possible control of seizure with minimal adverse effects for the pregnant individual and the child. Epilepsy-related complications during pregnancy include possible changes in seizure frequency, fluctuating ASM plasma levels, and possible teratogenic effects of ASMs.[96,97]

Despite multiple reports of both increased and decreased seizure frequency during pregnancy, a recent practice parameter update issued by the American Academy of Neurology (AAN) found that there was inconclusive evidence to support that pregnancy was associated with changes in seizure frequency. What was concluded, however, was that patients with epilepsy who were seizure free for at least 9 months to 1 year prior to pregnancy had a very high probability (84%-92%) of remaining seizure free during pregnancy.[96] However, if seizures are increasing during pregnancy, it is important to inquire about nonadherence in a normally adherent patient, as they may be concerned about the potential adverse medication effects on the developing fetus.[98]

Fluctuations in ASM concentration may be caused by physiologic changes that occur during pregnancy including reduced gastric motility, nausea and vomiting, increased medication distribution, increased renal elimination, altered hepatic enzyme activity as well as changes in protein binding.[95] Physiologic changes, such as changes in protein binding, can begin as early as the first 10 weeks of pregnancy, and may not normalize until 4 weeks postpartum (eg, protein binding of carbamazepine, phenobarbital, and phenytoin). Fluctuations in ASM plasma concentrations due to increased ASM clearance has been found to be true for lamotrigine, carbamazepine, phenytoin, oxcarbazepine, and levetiracetam.[96] Clinical consequences of ASM fluctuations are variable and some patients will not experience increased seizure frequency despite fluctuating levels. Patients on lamotrigine, however, have been found to undergo a 40% decrease in the ratio of plasma lamotrigine concentration to dose, resulting in deterioration of seizure control in approximately 75% of pregnant patients.[95] It is therefore recommended that ASM levels, particularly lamotrigine levels, be monitored closely during pregnancy, and that dosage increases occur over the course of the pregnancy if needed. This should be followed up with a rapid decrease in the postpartum period. Fluctuations have also been reported for phenobarbital, valproic acid, primidone, and ethosuximide, although strong evidence for this is lacking.[96]

Adverse pregnancy outcomes associated with ASM use include an increased risk of major congenital malformations (MCMs) compared to pregnant persons without epilepsy.[97] This risk is believed to be due to ASM exposure and not seizures, as infants born to patients with epilepsy who do not take ASMs have the same risk of birth defects as infants born to seizure-free individuals (2%-3%).[98] The most concerning effects are found with the use of valproic acid which is associated with a risk of MCMs that is 3.5 to 4 times that of offspring from patients without epilepsy, especially if taken during the first trimester of pregnancy.[97,99] Furthermore there is an increased risk of neurodevelopmental deficits, including effects on cognition, in children exposed to valproic acid *in utero*.[97,99] These effects are dose-dependent, and the risk of MCM significantly increases at 600 mg/day, with the greatest risk observed at doses that exceed 1,000 mg/day.[99] However, individual susceptibility is genetically determined, and teratogenicity can occur at much lower doses in some persons. Due to these findings, it is recommended that valproate should not be used in pregnant individuals or in female patients of child bearing potential with epilepsy and that withdrawal of valproate or switching to an alternative treatment should be considered.

Data on teratogenic risk with the newer agents are limited, although topiramate was reclassified from pregnancy category C to D due to an increased association with cleft palate (it may also have a negative effect on birth weight and cause increases in hypospadias).[50] In general, higher ASM doses, higher ASM serum concentrations, polytherapy (especially polytherapy with valproate), and a family history of birth defects increase the teratogenic risk of ASMs.[97] As such, the risk of birth defects is believed to have gone down with decreasing doses and decreasing use of polytherapy.

Deciding on the most effective single-medication treatment prior to conception is vitally important. Teratogenic effects of ASM must always be considered when choosing ASMs for patients of reproductive age, even when the plans are not to become pregnant, as many unplanned pregnancies occur and MCMs generally occur early in pregnancy before the patient is aware of their pregnancy. With proper counseling and management, more than 90% of these pregnancies will still have satisfactory outcomes. Updated practice parameters are available to aid in the selection of ASMs in pregnancy and the counseling and management of pregnant patients with epilepsy.[96,97,99]

Teratogenic effects may possibly be prevented by adequate folate intake. Although data are insufficient to show that folate is effective in preventing MCM in patients with epilepsy, there is no evidence of harm. Therefore, the AAN recommends that all females of childbearing potential, take at least 0.4 mg of folic acid prior to conception and during pregnancy. The AAN cites insufficient data to support a specific dose but prenatal vitamins containing folic acid 0.4 to 5 mg/day can be recommended.[100] Folate doses in the high range should be used in individuals with a history of a previous pregnancy with a neural tube defect or in those taking valproic acid. Additionally, some ASMs may possibly cause neonatal hemorrhagic disorder and there is a lack of strong evidence to determine if prenatal vitamin K supplementation can reduce this complication. However, vitamin K 10 mg/day is often administered orally to the pregnant person during the last month of pregnancy and/or administered parenterally to the newborn at delivery.[101]

Some ASMs pass into human milk and those with less protein binding will accumulate more. Treatment with ASMs is not necessarily a reason to discourage breastfeeding, although ASM concentrations are measurable in infants fed human milk. In fact, an argument could be made that since ASMs should rarely be discontinued abruptly, providing human milk after birth allows for a downward titration of a medication that the baby was exposed to for the past 9 months. Infants born to patients taking any ASM (particularly barbiturates or benzodiazepines) should be closely observed for signs of excess sedation, irritability, or poor feeding.[101,102] In general, FDA labeling of ASMs including valproate state that the developmental and health benefits of human milk should be considered along with the patient's underlying seizure disorder, their clinical need for that ASM, and any potential adverse effects from the ASM on the infant fed human milk. Additionally, FDA labeling states caution should be exercised when an ASM is administered to an individual providing human milk to an infant.

Therapeutic Considerations in Patients of Asian and South Asian Decent

A common idiosyncratic effect of ASMs is rash. However, in some cases, the rash can quickly progress to SJS, TEN, or DRESS, which are severe and life-threatening conditions. There is a strong association between the presence of an inherited variant of the *HLA-B* gene, *HLA-B*1502*, in these populations, and the risk of developing SJS/TEN with carbamazepine (and possibly phenytoin, lamotrigine, and oxcarbazepine as well).[18] This *HLA-B* variant is found in up to 15% of individuals from many Asian, Southeast Asian, and South Asian populations including Hong Kong, Thailand, Malaysia, Philippines, Taiwan, North China, India, and to a much lesser extent Japan and Korea. The variant is largely absent in individuals not of Asian origin. Testing for *HLA-B*1502* may be recommended for patients prior to initiation of carbamazepine, phenytoin, lamotrigine, or oxcarbazepine therapy in these high-risk populations. If the genetic testing is positive, these ASMs should generally be avoided. In addition, the *HLA* genotype *HLA-A*3101* is associated with multiple carbamazepine-induced cutaneous reactions in Chinese, Japanese, and European populations.[18] Many *HLA-B*1502*-positive and *HLA-A*3101*-positive patients treated with ASMs will not develop SJS/TEN or other hypersensitivity reactions, and these reactions can still occur infrequently in *HLA-B*1502*-negative and *HLA-A*3101*-negative patients of any ethnicity. Of those who do experience SJS/TEN with carbamazepine, 90% will have this reaction within the first few months of treatment.[18]

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of therapy for all ASMs is seizure freedom or reduction in seizure frequency, while minimizing adverse medication reactions. Determining clinical response to treatment involves identifying the number and type of seizures and adverse medication reactions during the monitoring and follow-up phase of treatment. Providing the patient with a seizure and adverse reactions diary will assist in this effort as the severity and frequency of seizures should be monitored by the patient and the family and recorded in the seizure diary. External factors such as seizure triggers can also influence seizure frequency. Therefore, patients should be educated that seizure triggers should be identified and documented because avoiding them may have a significant impact on seizure control. Additionally, although seizures tend to be stereotyped within an individual, the clinical presentation of the seizure may change over time or with treatment and this should be documented. During all follow-up visits, the seizure diary should be reviewed with both patients and family to determine whether patients are truly seizure free.

Patients should also be monitored for all ASM adverse reactions and assessed for dose-related CNS effects (eg, drowsiness, fatigue, dizziness, blurry vision, and incoordination). Such adverse reactions are common, especially when initiating ASM therapy as well as with polytherapy. If possible, CNS adverse reactions should be avoided, either by dose reduction of monotherapy, reduction or elimination of polytherapy, or substituting for a better tolerated ASM.

Patients should also be assessed for idiosyncratic adverse reactions which usually require withdrawal in an affected patient, including serious rash (ie, SJS, TEN), hematologic dyscrasias, electrolyte abnormalities (eg, hyponatremia), and hepatotoxicity. Laboratory assessment, including complete blood cell (CBC) counts, chemistries, and liver function tests, should be performed at baseline and after initiation of ASMs to monitor for idiosyncratic adverse reactions. Other specific laboratory tests can be performed if there is clinical suspicion of adverse reactions (eg, measuring ammonia levels in a patient with suspected hyperammonemic encephalopathy from valproic acid). Acute organ failure due to an idiosyncratic reaction, when it occurs, generally occurs within the first 6 months of ASM therapy,[103] although there is a delay between treatment initiation and the onset of symptoms. There is also a more rapid onset if a patient who has had an idiosyncratic reaction to a specific ASM is rechallenged.[103]

Patients on chronic ASM therapy should be monitored for long-term medication adverse effects. Specifically, for those patients on chronic ASMs known to cause osteoporosis (eg, phenytoin and phenobarbital), bone density loss can be measured via bone-density scanning (eg, DEXA) after many years of treatment. Gums should be visually inspected for gingival hyperplasia at follow-up (eg, phenytoin) and patients should also be instructed to have regular and thorough dental care.

Medication adherence should also be monitored and when seizures are not controlled, medication nonadherence must always be considered, as it is the single most common reason for treatment failure. It is estimated that up to 60% of patients with epilepsy are nonadherent.[104] The rate of nonadherence is increased by the complexity of the regimen and by doses taken three and four times a day.[104] Frequent uncontrolled seizures can also predispose a patient to nonadherence secondary to confusion over whether the medication was taken. Nonadherence is not influenced by age, sex, psychomotor development, or seizure type.[104]

Obtaining serum concentrations of ASMs is a method by which to optimize therapy for an individual patient, but is not a therapeutic end point in itself. A patient’s clinical response is more important than the actual serum medication concentration as seizure control can occur before the “minimum” of the published therapeutic range is achieved, and adverse medication effects can appear before the “maximum” of the range is achieved. Some patients may need and tolerate concentrations beyond the maximum. Clinicians should define a therapeutic range for an individual patient as the concentration below which there are adverse effects and above which the patient experiences seizures. Then serum levels can be useful to document lack of efficacy, loss of efficacy, and to determine how much room there is to increase a dose based on expected toxicity. Serum levels can also be particularly useful to determine nonadherence and should be checked if there are questions. Depending on the ASM, serum levels can also be useful in patients with significant renal and/or hepatic disease, patients taking multiple agents, and individuals who are pregnant or taking OCs.[36,77]

Patients should also be monitored long term for comorbid conditions, social adjustment (including QOL assessments), and medication interactions.

Periodic screening for comorbid neuropsychiatric disorders, such as depression, suicidal ideation, and anxiety, is also important. Screening for learning and development issues in children is also imperative as neurodevelopmental comorbidities commonly coexist with epilepsy and may be associated with use of ASMs.[2]

Overall treatment outcomes are increasingly focusing on obtaining an optimal QOL for the patient and the AAN has developed quality performance measures for the clinician that define a high quality of care of these patients. Among those performance measures, it is important to remember to counsel patients about ASM adverse reactions and initiate a discussion about depression. Additionally, factors that can impact QOL in patients with epilepsy which should be addressed include issues about driving, economic security, forming relationships, and epilepsy safety such as precautions when swimming, social isolation, and social stigma.[2,32]

⑩ After the initiation of treatment, approximately 65% of patients treated for new-onset epilepsy can be expected to be maintained on one ASM and may be seizure free.[34] The percentage of patients who are seizure free on one ASM varies by seizure type. After 12 months of treatment, the percentage who are seizure free is highest for those who have only GTC seizures (48%-55%), lowest for those who have only focal seizures (23%-26%), and intermediate for those with mixed seizure types (25%-32%).[102,105]

Polytherapy with two or more ASMs is appropriate for patients who cannot achieve seizure freedom on ASM monotherapy. Of the 35% of patients with unsatisfactory control on monotherapy, 10% will be well controlled with a two-ASM treatment. Of the remaining patients, 20% will continue to have unsatisfactory control despite greater than two-ASM treatment and are deemed to be medication resistant.[34] The ILAE consensus definition for medication-resistant epilepsy includes lack of seizure freedom from at least two adequate trials of an ASM as monotherapy or polytherapy, which were appropriately chosen and used.[103] Those who have unsatisfactory control despite multiple ASM treatment may be candidates for the ketogenic diet, a vagal nerve stimulator, and/or surgery, which is especially encouraged for those who are good surgical candidates. In fact, the AAN has included assessment about patient knowledge and referral to surgery in their quality performance measures.[32]

For a patient with long-standing epilepsy, adequacy of their current medication regimen, whether they are seizure free or not, should be routinely evaluated. Reevaluate goals when necessary, especially in those 20% to 35% of patients where seizure freedom cannot be achieved, as obtainable goals which balance seizure control with patient-specific QOL factors[2,32] and wishes (eg, decrease in the number of seizures with minimized medication adverse effects) should be established. Patient education and assurance of patient understanding of the goals is also an essential part of the care plan.

For some patients who have not experienced seizures for many years and who are deemed to have a low risk of recurrence, ASM withdrawal may be considered. The AAN has issued guidelines for discontinuing ASMs in seizure-free patients.[106] After assessing the risks and benefits to both the patient and society, ASM withdrawal can be considered in a patient meeting the following profile: seizure free for 2 to 5 years, a history of a single type of focal seizure or primary generalized seizures, a normal neurologic exam and normal IQ, and an EEG that has normalized with treatment.[107,108] When these factors are present, the relapse rate at 1 year is expected to be 35% and 29% at 2 years.[109] For those patients who relapse after withdrawal, ASMs can be restarted; while seizure freedom can be regained for most patients who restart ASMs, it does not happen for all.[110] Factors associated with a poor prognosis in discontinuing ASMs, despite a seizure-free interval, include a history of a high frequency of seizures, repeated episodes of status epilepticus, a combination of seizure types, and development of abnormal mental functioning.[107,108]

CONCLUSION

Epilepsy is a group of diseases that present with variable signs and symptoms and is a major burden in terms of QOL, morbidity, and risk of premature mortality from SUDEP, especially in those who continue to have seizures. Pharmacologic management of epilepsy consists of symptomatic treatment only. The mainstay of pharmacologic therapy is ASMs, with a goal of suppression of seizure occurrence. Over the years, over two dozen ASMs with various mechanisms of action, pharmacokinetics, adverse effect profiles, and interaction profiles have become available for the treatment of epilepsy. When selecting ASM therapy, efficacy must be balanced with ASM adverse effects and cost and take into consideration patient-specific factors including age, sex, susceptibility to adverse effects, concomitant medications, and ability to adhere with selected regimen. Suppression of seizures can be achieved with ASM monotherapy or polytherapy in up to two-thirds of all patients with epilepsy but do not alter long-term prognosis. In patients with medication-resistant epilepsy, nonpharmacologic options such as ketogenic diet, vagal nerve stimulation, and epilepsy surgery should be considered. Epilepsy surgery is the most effective way to achieve long-term seizure freedom, but is an option for only a few people with medication-resistant epilepsy. With improved understanding of epilepsy pathophysiology and pathogenesis, better, disease modifying, and curative pharmacological treatments may become available.

ABBREVIATIONS

AAN	American Academy of Neurology
AES	American Epilepsy Society
AMPA	α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid
ASM	antiseizure medication
AUC	area under the medication concentration time curve
BECT	benign epilepsy with centro-temporal spikes
CAE	childhood absence epilepsy
C_{max}	maximal blood medication concentration
CT	computed tomography
DEXA	dual energy x-ray absorptiometry
DRESS	drug reactions with eosinophilia and systemic symptoms
EEG	electroencephalogram
EFHC1	EF-hand containing protein-1
GABA	γ-aminobutyric acid
GTC	generalized tonic–clonic
IGE	idiopathic generalized epilepsy
ILAE	International League Against Epilepsy
LGS	Lennox–Gastaut syndrome
JME	juvenile myoclonic epilepsy
MCMs	major congenital malformations
MRI	magnetic resonance imaging
NMDA	*N*-methyl-D-aspartate
OC	oral contraceptive

PCOS	polycystic ovary syndrome
QOL	quality of life
REMS	risk evaluation and mitigation strategy
SCARs	severe cutaneous adverse reactions
SE	status epilepticus
SJS	Steven–Johnsons syndrome
SP	simple partial
SUDEP	sudden unexplained death in epilepsy
TEN	toxic epidermal necrolysis
T_{max}	time to maximal blood medication concentration
VNS	vagus nerve stimulation
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. At what age is the incidence of epilepsy the highest?

   A. Childhood

   B. Adolescence

   C. Older adult

   D. Both A and C

2. The key feature of generalized-onset seizures is

   A. Onset encompassing the entire brain.

   B. Onset in a network of cells in one hemisphere.

   C. Onset in a network of cells distributed bilaterally.

   D. Spread to both hemispheres.

3. The key feature of focal unaware seizures is

   A. Onset in one hemisphere.

   B. Impaired awareness.

   C. Retained awareness.

   D. Evolution to bilateral convulsions.

4. Nonpharmacologic therapy of the epilepsy patient can involve all of the following in the appropriate patient *except*

   A. Temporal lobe surgery

   B. Low glycemic index diet treatment

   C. Acupuncture

   D. Vagal nerve stimulator

5. Which ASM is *most* associated with major congenital malformations?

   A. Lamotrigine

   B. Topiramate

   C. Levetiracetam

D. Valproic acid/divalproex

6. Which ASM may aggravate other seizure types in childhood absence epilepsy, a generalized-onset epilepsy?

   A. Phenytoin

   B. Valproate/divalproex

   C. Ethosuximide

   D. Levetiracetam

7. Which ASM is a CYP450 inhibitor?

   A. Carbamazepine

   B. Phenytoin

   C. Phenobarbital

   D. Valproic acid/divalproex

8. Which ASM has saturable GI absorption at large doses?

   A. Gabapentin

   B. Tiagabine

   C. Levetiracetam

   D. Lacosamide

9. Which ASM is often associated with increased irritability?

   A. Felbamate

   B. Clobazam

   C. Levetiracetam

   D. Lamotrigine

10. Patient H has a history of calcium phosphate kidney stones and is allergic to sulfa. Which is the *worst* choice of ASM to use in the treatment of this patient's partial seizures?

    A. Lacosamide

    B. Zonisamide

    C. Carbamazepine

    D. Oxcarbazepine

11. Which ASM is more likely to cause word-finding problems?

    A. Valproic acid/divalproex

    B. Tiagabine

   C. Phenytoin

   D. Topiramate

12. Which ASM is associated with an increased risk of rash including SJS if the recommended dose escalation is exceeded?

   A. Peramapnel

   B. Lamotrigine

   C. Eslicarbazepine

   D. Clobazam

13. Which ASM is associated with irreversible vision loss after long-term use?

   A. Vigabatrin

   B. Lacosamide

   C. Valproic acid/divalproex

   D. Rufinamide

14. In a patient taking an enzyme-inducing ASM, which form of birth-control does *not* need a back-up method to avoid pregnancy?

   A. Transdermal contraceptive patch

   B. Emergency contraceptive pill

   C. Oral contraceptive pills

   D. Hormone-releasing intrauterine device system

15. A drug-resistant epilepsy patient is one who has failed:

   A. One drug

   B. Two drugs

   C. Three drugs

   D. More than three drugs

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** While epilepsy is a chronic disease that can present at all ages, the highest number of new epilepsy cases will present in childhood and the older population. New epilepsy cases presenting in childhood are often of genetic origin and epilepsy cases presenting in the older population are usually acquired due to brain injury (eg, stroke).

2. **C.** Generalized-onset seizures start in bilaterally distributed networks (eg, a network encompassing both sides of the brain) and not necessarily everywhere in the brain (see Fig. 75-1).

3. **B.** A focal unaware seizure corresponds to the prior term "complex partial seizure" and its distinguishing feature is impaired awareness at any time during a focal seizure (Fig. 75-1). The distinguishing feature of focal seizures (both unaware and aware) is its onset in one hemisphere.

4. **C.** Epilepsy surgery, including temporal lobe surgery, ketogenic diet which is a low glycemic index diet treatment, and vagal nerve stimulation are all

nonpharmacologic therapies that have benefit in decreasing seizure frequency in epilepsy. Acupuncture does not have benefit in epilepsy.

5. **D.** Valproic acid/divalproex especially has a number of unique adverse effects including a well-known teratogenicity and is pregnancy category D in epilepsy and pregnancy category X for migraine prevention (Table 75-5).

6. **A.** Both phenytoin and carbamazepine are very efficacious in focal-onset seizures and have known efficacy in controlling tonic–clonic seizures but may exacerbate other generalized seizures and should be used with caution in generalized-onset epilepsy, especially generalized atypical absence (Table 75-5).

7. **D.** Valproic acid/divalproex is an inhibitor of CYP450 and UGT metabolism and inhibits the metabolism of the first-generation ASMs as well as other ASMs and drugs that go through similar CYP450 and UGT pathways (Tables 75-3 and 75-5).

8. **A.** Gabapentin relies on the L-amino acid carrier protein in the gut and the CNS to be actively transported across those membranes. As binding is saturable this causes a dose-dependent bioavailability, with decreasing bioavailability with increasing dose as the transporter is believed to be saturated at doses ≤ 1,200 mg per single dose.

9. **C.** Levetiracetam is well-recognized for causing irritability in many patients, an effect which may be lessened with dose reduction (Table 75-5). There is increasing recognition of the unusually high prevalence of irritability and its impact on QOL with levetiracetam.

10. **B.** Zonisamide is contraindicated in those with sulfa allergy and is associated with a rare risk of renal stones (Table 75-5).

11. **D.** Word-finding difficulties and cognitive slowing have been commonly reported to occur (Table 75-5) especially during rapid titration and with high doses of topiramate.

12. **B.** Lamotrigine can cause rash (Table 75-5), usually appearing after 3 to 4 weeks of therapy, and is typically generalized, erythematous, and morbilliform, but can progress to Steven–Johnson syndrome. Rashes are more likely to occur if the patient has had a prior rash to another ASM and risk factors for more serious rashes include concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used.

13. **A.** Vigabatrin may cause progressive, irreversible, bilateral concentric visual field constriction in a high percentage of patients and may also reduce visual acuity in a dose-related and life exposure–related manner (Table 75-5).

14. **D.** Enzyme-inducing ASMs can cause treatment failures in patient's taking oral OCPs due to increased metabolism of ethinyl estradiol and progestin. It is unclear if there is an effect of ASMs on the transdermal contraceptive patch or the emergency contraceptive pill but it has been suggested that individuals use twice the normal dose of emergency contraception. Medroxyprogesterone depot injections and hormone-releasing intrauterine systems, on the other hand, are not similarly affected by ASMs.

15. **B.** The ILAE consensus definition for drug-resistant epilepsy includes lack of seizure freedom from at least two adequate trials of ASM monotherapy or polytherapy, which were appropriately chosen and used.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 76: Status Epilepticus

Elizabeth A. Hall; Stephanie J. Phelps; James W. Wheless

KEY CONCEPTS

KEY CONCEPTS

1 Status epilepticus (SE) is a neurologic emergency that may be associated with significant morbidity and mortality.

2 Generalized convulsive status epilepticus (GCSE) is defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. Any seizure that does not stop within 5 minutes should be treated aggressively as impending SE.

3 There are two types of SE, GCSE and nonconvulsive status epilepticus (NCSE). GCSE is the most common type and is divided into four stages: (1) impending, (2) established, (3) refractory, and (4) super-refractory.

4 The pathophysiology of GCSE is unknown; however, experimental models show a dramatic decrease in γ-aminobutyric acid (GABA)–mediated inhibitory synaptic transmission and that glutamatergic excitatory synaptic transmission sustains the seizures.

5 During prolonged GCSE, $GABA_A$ receptors move from the synaptic membrane into the cytoplasm, becoming functionally inactive. Receptor loss on the synaptic surface may result in time-dependent benzodiazepine pharmacoresistance. Glutamatergic *N*-methyl-D-aspartate (NMDA) receptors also increase in number and activity, suggesting a role for ketamine.

6 Treatment is done to prevent or decrease morbidity and mortality of prolonged seizures. Pharmacologic treatment needs to be rapid and aimed at terminating both electrical and clinical seizures. The probability of poorer outcomes increases with an increased length of electroclinical seizure activity.

7 IV lorazepam is the preferred benzodiazepine for initial treatment of GCSE given its efficacy and long duration of action in the central nervous system (CNS), although IM midazolam, IV lorazepam, IV diazepam, and IV phenobarbital effectively terminate seizures lasting at least 5 minutes. Midazolam is the preferred benzodiazepine for IM and intranasal administration in patients without an established IV.

8 The hydantoins (ie, phenytoin, fosphenytoin) continue to be the long-acting antiseizure medications used most frequently, although this is changing. The comparative efficacy of these two antiseizure medications is still unknown; however, fosphenytoin is better tolerated and hence preferred. Either should be given concurrently with benzodiazepines.

9 The second antiseizure medication administered is less effective than the first “standard” antiseizure medication in both adults and pediatric patients. The third antiseizure medication may be significantly less effective.

10 If GCSE is not controlled by two antiseizure medications (a benzodiazepine and a standard antiseizure medication), it is considered refractory. In these cases, anesthetic doses of midazolam, pentobarbital, or propofol may be used and monitored with a continuous electroencephalogram (EEG).

BEYOND THE BOOK

BEYOND THE BOOK

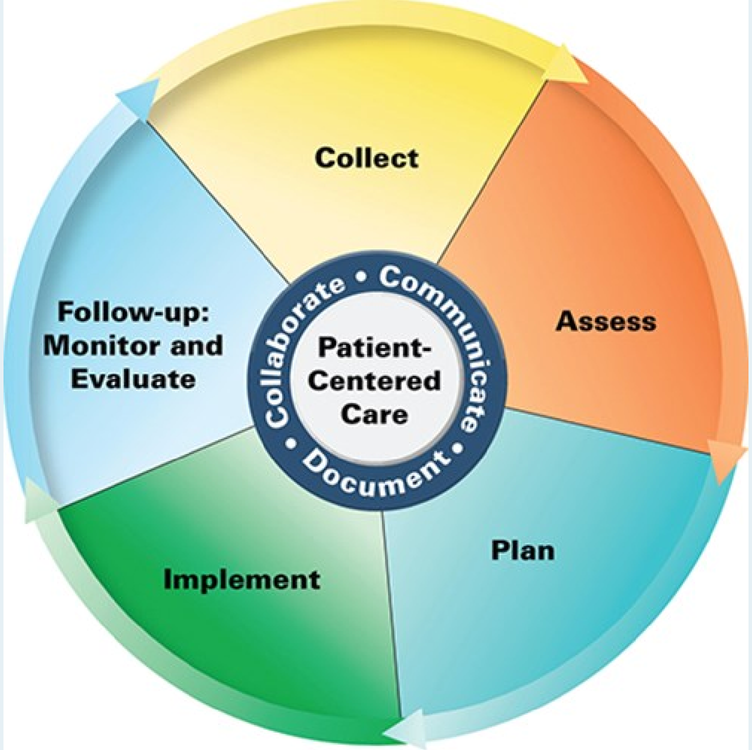
Case Question: An order is written for a 15-mg PE/kg fosphenytoin loading dose for a 60-kg patient. The dose is added to 50 mL of an appropriate fluid and is given at the maximum administration rate. There are questions about the rate settings for the infusion device (mL/min) and how long it will take to infuse the dose. Complete the following table.

Product information	Parenterally Administered Product							
	Phenytoin	Fosphenytoin	Valproate	Levetiracetam	Phenobarbital	Diazepam	Lorazepam	Midazolam
Refrigeration required yes/no								
Pharmaceutical Vehicle—Propylene glycol: yes/no								
pH of product								
Maximum infusion rate								
Compatible admixture solution(s)*								
IM administration, yes/no								
Cardiac monitoring required								
Reference range (mg/L)								

Solution to be infused, not reconstituted

PATIENT CARE PROCESS

Patient Care Process for Status Epilepticus



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect *(some items may be deferred to a later time due to time constraints associated with a medical emergency)*

- Patient characteristics (eg, age, weight, height)
- Time of seizure onset and duration of seizure activity (see Table 76-2)
- Past medical history (eg, known epilepsy and type or prior seizure, medication-allergies) (see Table 76-1)
- Social history (eg, ethanol use, unhealthy substance use, ketogenic diet)
- Complete a medication history of current prescription, over-the-counter (OTC) medications, herbals products, and dietary supplements, including any recently started or stopped medications (prescription or nonprescription)
- Information (eg, agent, route, dose, response) regarding antiseizure medications administered immediately prior to emergency department/hospitalization
- Objective data
    - Temperature, blood pressure, heart rate, respiratory rate, oxygen (O_2) saturation, arterial blood gases
    - Serum chemistries (eg, electrolytes, glucose, magnesium, renal/hepatic function studies); complete blood count (CBC) with differential and blood/urine cultures; urine toxicology screen; and serum antiseizure medication concentrations
    - Electroencephalogram (EEG), computed tomography (CT), magnetic resonance imaging (MRI) as needed

Assess

- If appropriate, assess medication adherence to antiseizure medications prior to admission and correct delivery of antiseizure medications during hospitalization
- Evaluate the appropriateness, effectiveness, and safety of all chronic or acute prescription and nonprescription medications. Check serum medication concentration for an “effective” or “safe” concentration (see Table 76-4)
- Airway (arterial blood gases, respiratory rate [RR]) and cardiac (blood pressure [BP], heart rate [HR]) stability
- Temperature for the presence of fever
- Possible seizure etiologies (eg, known epilepsy, febrile, infectious, head trauma/cerebral vascular accident [CVA], substance-associated, low antiseizure medication serum concentrations) (see Table 76-3)
- Presence of seizure provoking factors (eg, ethanol, unhealthy substance use, adverse medication/herbal effect, medication interactionw, low or elevated antiseizure medication serum concentration) (see Table 76-3)
- Duration of seizure activity and characteristics of the seizure (see Table 76-2)
- Available laboratory studies
- Need for adjusted dosing based on organ function (eg, liver, kidney function), serum albumin, weight

Plan*

- Management of nonepileptic causes for seizure (eg, opioid overdose, electrolytes imbalance) (see Table 76-3 and Fig. 76-1)
- Management of impending seizure activity (initial phase) including agent, dose, route, and method of administration, including the option for alternative agents and need for a second dose (see Table 76-2 and Fig. 76-1)
- Need for concurrent pharmacotherapy including thiamine and glucose, pyridoxine, antipyretic, and empiric antibiotics (see Fig. 76-1)
- First-line antiseizure medication regimens for the second phase (established stage), including agent, dose, method of administration, and frequency, including the option for a second dose if needed (see Tables 76-2 and 76-4 and Fig. 76-1)
- Anesthetic medications for the third phase (refractory GCSE stage) including agent, dosage, method of administration accompanied by a plan to titrate and withdraw therapy (see Tables 76-2 and 76-6 and Fig. 76-1)
- Monitor for effectiveness and safety of antiseizure medications including serum concentration and medication interactions during the management of GCSE (see Table 76-5)
- Pharmacotherapy in transfer to a nonintensive care unit setting or discharge home, including the transition to oral therapy and subsequent monitoring of serum antiseizure medication concentrations (see Table 76-4)
- Rescue therapies in the home environment, including need, agent, dose, method of administration, and plan should first dose fail. Need for cardiopulmonary resuscitation (CPR) training
- Patient and/or legal guardian medication education at discharge, including correct use of rescue therapies

Implement*

- Ensure all medications are ordered, that the dosage is appropriate, and discontinued as appropriate, during the patient’s transition from home to the emergency department (ED), ED to hospitalization, and home (see Tables 76-4 and 76-6)
- Ensure all medications are dispensed as prescribed (see Tables 76-4 and 76-6)
- Ensure all antiseizure medications are administered and monitored correctly (see Table 76-5)

Follow-Up: Monitor and Evaluate

- Antiseizure medication effectiveness in stopping clinical and electrical seizure activity
- Presence of adverse medication reactions or medication interactions (see Table 76-5)
- Therapeutic medication monitoring performed as needed with subsequent interpretation

Collaborate with patient, caregivers, and other healthcare professionals.

INTRODUCTION

①② Status epilepticus (SE) is a common neurologic emergency associated with brain damage and death. The Commission on Classification and Terminology and the Commission on Epidemiology of the International League Against Epilepsy (ILAE) defines SE as a situation where there is a failure of the mechanisms responsible for seizure termination and prevention of prolonged seizures. There are two operational dimensions to this new definition. First, the length of the seizure and the time point beyond which the seizure is regarded as “continuous seizure activity”; usually 5 minutes. Second is the time of ongoing seizure activity, after which there is a risk of long-term consequences (30 minutes). Both time points are based on animal experiments and clinical research; hence, they should be considered current best estimates.[1] The traditional definition defines SE as (a) any seizure lasting longer than 30 minutes whether or not consciousness is impaired or (b) recurrent seizures without an intervening period of consciousness between seizures.[2] Clinically, this definition is limited, as the average seizure is less than 2 minutes in length and only 40% of seizures lasting 10 to 29 minutes cease without treatment.[3] Pharmacoresistance and mortality significantly increase with prolonged seizure duration. Therefore, aggressive treatment of seizures lasting 5 or more minutes is strongly recommended. It is important to note that SE can present in several forms (Table 76-1), including generalized convulsive status epilepticus (GCSE) and nonconvulsive status epilepticus (NCSE).

Table 76-1

International Classification of Status Epilepticus

Convulsive		Nonconvulsive	
International	Traditional Terminology	International	Traditional Terminology
Generalized SE - Tonic-Clonic[a,b] - Tonic[c] - Clonic[c] - Myoclonic[b] - *Erratic*[d]	Grand mal, epilepticus convulsivus	Absence[c]	Petit mal, spike-and-wave stupor, spike and-slow-wave or 3/s spike-and-wave, epileptic fugue, epilepsiaminora continua, epileptic twilight, minor SE
Secondary generalized SE[a,b] - Tonic - Partial seizures with secondary generalization		- Partial SE[a,b] - Simple partial - Somatomotor - Dysphasic - Other types - Complex partial	- Focal motor, focal sensory, epilepsiapartialis continua, adversive SE - Elementary - Temporal lobe, psychomotor, epileptic fugue state, prolonged epileptic stupor, prolonged epileptic confusional state, continuous epileptic twilight state

SE, status epilepticus.

[a] Most common in older children.

[b] Most common in adolescents and adults.

[c] Most common in infants and young children.

[d] Most common in neonates.

Nonconvulsive status epilepticus accounts for up to 20% of all SE cases. It has variable and subtle clinical symptoms, such as cognitive impairment, automatisms, and/or behavioral changes, which make diagnosis challenging.[4] Electroencephalogram (EEG) is an important diagnostic and management tool. A benzodiazepine is the medication of choice for initial treatment, and intravenous (IV) phenytoin, valproic acid, or levetiracetam may be used as second-line.[4] In refractory cases, non-anesthetic antiseizure medication (ASMs), such as lacosamide and topiramate, are typically preferable to IV anesthetic medications, such as midazolam, propofol, and barbiturates.[4]

③ GCSE is the most common and severe form of SE. It is characterized by repeated primary or secondary generalized seizures involving both hemispheres of the brain which result in a loss of consciousness, and a persistent postictal state. GCSE can be divided into four phases: (1) stabilization, (2) initial therapy, (3) secondary therapy, and (4) third therapy (Table 76-2).[5]

Table 76-2

Generalized Convulsive Status Epilepticus

Phase	Time	Stage	Definition
Stabilization phase	0-5 minutes		An acute condition characterized by convulsive seizures. This may include pre-hospitalization or emergency room care
Initial-therapy phase	0-20 minutes	Impending GCSE	
Second-therapy phase	20-40 minutes	Established GCSE	An acute condition characterized by continuous seizures for at least 20 minutes, or by 20 minutes of intermittent seizures without full recovery of consciousness between events
Third-therapy phase	40-60 minutes	Refractory GCSE	An acute condition characterized by continuous seizures despite initial treatment with two ASMs
	>24 hours	Super-refractory	An acute condition characterized by seizures that continue 24 hours or longer after the administration of anesthesia, including cases in which SE recurs on reduction or withdrawal of anesthesia

ASM, antiseizure medication; GCSE, generalized convulsive status epilepticus; SE, status epilepticus.

EPIDEMIOLOGY

The worldwide incidence of GCSE varies considerably and has ranged from 5.1 to 41 per 100,000, with the incidence being highest in developing countries.[6] GCSE does not have a predilection for gender,[6] and occurs more frequently in nonwhites across all ages.[7] The incidence is highest in those less than 2 years of age[8] and older than 60 years of age.[6] Economic income may contribute to a difference in overall incidence.[6] Most GCSE occurs in individuals with no history of epilepsy; however, approximately 5% of adults and 10% to 25% of children with epilepsy will develop GCSE.

ETIOLOGY

Precipitating events for GCSE vary and generally reflect different populations and referral patterns. Most episodes in individuals with epilepsy occur because of acute antiseizure medication withdrawal, a metabolic disorder or concurrent illness, or a preexisting neurologic disease progression. Common etiologies and mortality rates are shown in Table 76-3.[7,9] Precipitating events are divided into those with or without neurologic structural lesions or those with a precipitating injury or insult. Cases with structural lesions or those with a specific neurologic insult are associated with a poor prognosis.

Table 76-3

Etiology and Mortality for Pediatric and Adult Cases of Status Epilepticus

Etiology	Mortality Number of Cases (%)	Mortality Number of Cases (%)
	n = 200 Cases of Pediatric SE	*n* = 512 Cases of Adult SE
Type I (No Structural Lesion)		
Infection	55 (5)	6 (35)
CNS infection	11 (0)	2 (20)
Metabolic	20 (5)	12 (36)
Low ASM levels	16 (0)	24 (7)
Alcohol	0 (0)	13 (8)
Idiopathic	6 (0)	13 (18)
Type II (Structural Lesion)		
Anoxia/hypoxia	27 (13)	14 (65)
CNS tumor	3 (50)	5 (22)
CVA	5 (0)	26 (27)
Substance overdose	5 (0)	3 (23)
Hemorrhage	5 (11)	4 (35)
Trauma	13 (0)	3 (23)
Remote causes[a]	33 (5)	7 (13)

ASM, antiseizure medication; CVA, cerebrovascular accident; SE, status epilepticus.

Percentages do not add up to 100% because some patients have multiple etiologies.

[a] More than half of the remote causes were congenital malformations and CVA in pediatric and adult patients, respectively.

Data from References 7,9.

Thtre are significant differences in pediatric and adult etiologies (see Table 76-3). During their first few weeks of life, infants born to mothers with substance uses can develop medication withdrawal seizures. Other neonates can develop GCSE due to a pyridoxine deficiency, which should resolve after IV pyridoxine (100 mg). In young children, the cause is often a nonspecific illness such as fever and/or a viral illness; however, in those less than one, acute encephalopathy and metabolic disorders are major causes of GCSE. In adults, the most frequent precipitating events are cerebrovascular disease, rapid antiseizure medication withdrawal, and low antiseizure medication serum concentrations. Cerebrovascular disease is the leading cause in those who have their first seizures after age 60. Prescription, OTC, herbal, and unhealthy substance use should be considered in anyone with new-onset GCSE.

PATHOPHYSIOLOGY

Seizures occur when excitatory neurotransmission overcomes inhibitory impulses in one or more brain regions. After a single, brief, generalized tonic-clonic seizure (less than 5 minutes), the seizure threshold is significantly elevated. And the brain's inhibitory mechanisms restore the balance of normal neurotransmission and prevent runaway excitation. In GCSE, the mechanisms that control normal brain homeostasis fail, which results in seizures occurring in close succession. In a different scenario, the magnitude of the proconvulsant stimulus is severe, and the compensatory mechanisms can be overwhelmed. In both instances, the mechanisms behind these failures are unknown, and the seizures become self-sustaining.

④Cellularly, it appears that an imbalance between excitatory (eg, glutamate, calcium, sodium, substance P, and neurokinin B) and inhibitory neurotransmission (eg, γ-aminobutyric acid [GABA], adenosine, potassium, neuropeptide Y, opioid peptides, and galanin) results in a seizure.[10] More specifically, $GABA_A$-mediated inhibition becomes less effective, while at the same time, glutamate's excitatory actions become enhanced. Thus, these mechanisms influence how GCSE progresses to refractory disease and impacts decisions related to sequencing antiseizure medications.

Most research has focused on gated ion channels; however, GCSE is largely caused by glutamate acting on postsynaptic *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA)/kainate receptors.[10] During GCSE, NMDA subunits are recruited to the synaptic membrane, where they form additional proconvulsant receptors. Glutamate's activation of NMDA and AMPA receptors causes gated calcium and sodium channels to open, leading to neuronal depolarization.[11] Sustained depolarization may maintain GCSE and eventually cause neuronal death through calcium-, free radical–, and kinase-mediated events.[12] Although medications acting as NMDA and AMPA receptor antagonists seem attractive, glutamate is likely not the sole mechanism for sustaining GCSE, and these other mechanisms become increasingly crucial as seizure duration increases.

⑤Within minutes of repetitive seizures, receptor trafficking occurs (eg, metabotropic GABA and glutamate receptors), as the $GABA_A$ postsynaptic receptors control chloride channels to produce hyperpolarization (inhibition) of the postsynaptic cell membrane.[11] These receptors have binding sites for GABA and select antiseizure medications (eg, phenobarbital and benzodiazepines) enhance $GABA_A$-mediated chloride inhibitory currents. It was previously thought that decreased presynaptic GABA led to prolonged seizures; however, it is currently held that GABA concentrations increase during the early phases of GCSE and continue to be elevated during late GCSE. During prolonged seizures, postsynaptic $GABA_A$ receptors experience endocytosis as the receptors move from the synaptic membrane into the cytoplasm. This results in a decrease in the number of γ_2 and $\beta_{2\text{-}3}$ subunits that are functionally active, decreasing response to both endogenous GABA and GABA agonists.[10] The γ_2 subunit is associated with benzodiazepine effectiveness; hence, a loss of these on the synaptic surface would result in time-dependent pharmacoresistance to a benzodiazepine. Clinically, benzodiazepine relative potencies can be reduced up to 20-fold if seizures persist for more than 30 minutes.[11] For this reason, a benzodiazepine should always be combined with another medication that acts differently. A similar phenomenon occurs with sodium channel antagonists (phenytoin); however, the magnitude of resistance is less.

As GCSE persists, complex pathophysiologic and biochemical changes lead to systemic alterations, progression of motor phenomena, and development of specific EEG findings.[12] Although these systemic complications affect the prognosis of GCSE, a prolonged seizure can destroy neurons independent of these events.[11] In fact, the systemic effects of induced seizures in animals can be blocked, but the damage to the neocortex, cerebellum, and hippocampus persists. Two distinct and predictable phases have been identified. Phase I occurs during the first 30 minutes of seizure activity, and phase II immediately follows.[12]

During phase I, each seizure markedly increases plasma epinephrine, norepinephrine, and steroid concentrations, resulting in hypertension, tachycardia, and cardiac arrhythmias. Within minutes, arterial systolic pressures can rise to above 200 mm Hg, and heart rate can increase by 83 beats per minute.[12] Mean arterial pressure does not fall below 60 mm Hg (8.0 kPa); hence, cerebral perfusion pressure is not compromised. In animals, cerebral blood flow is also increased, thereby protecting neurons from hypoxic injury.

In the presence of a hypoxic myocardium, seizure-induced increases in sympathetic and parasympathetic stimulation of the heart can result in ventricular arrhythmias.[12] Autonomic neuron stimulation can cause a release of insulin and glucagon. Concurrently, circulating catecholamines cause an elevation of hepatic cyclic adenosine monophosphate, producing glycogenolysis. Although the patient can be hyperglycemic initially, serum glucose begins to fall.[12]

Seizure-induced muscular contractions and hypoxia cause lactic acid release, producing severe acidosis accompanied by hypotension and shock. Muscle contractions can contribute to severe rhabdomyolysis with secondary hyperkalemia and acute tubular necrosis. The airway can be obstructed, causing cyanosis or hypoxia. Additionally, an increase in salivation and tracheal and pulmonary secretions can cause aspiration pneumonia. Although transient pleocytosis can develop, it should not be attributed to SE until infectious causes have been eliminated. Between seizures, the EEG slows, and blood pressure normalizes, and although metabolic demands increase, the brain can compensate adequately.

When seizures exceed 30 minutes (phase II), the EEG ictal discharge and clonic motor activity become continuous, and the patient begins to decompensate.[12] Despite elevated levels of catecholamines, the patient can become hypotensive. During this time, cerebral blood flow autoregulation becomes dependent on mean arterial pressure and begins to fail. Excessive oxygen and glucose consumption continues; however, compensatory mechanisms are no longer able to meet demands.

During phase II, the serum glucose concentration may be normal or decreased. Profound hypoglycemia, secondary to hyperinsulinemia, can occur in those with hepatic dysfunction or reduced glycogen stores.[12] Hyperthermia and respiratory deterioration with hypoxia and ventilatory failure can develop, and there may be increased sweating and salivation. Metabolic and biochemical complications, including respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and azotemia, may develop.

Morbidity and Mortality

Generalized convulsive status epilepticus is harmful to the brain. While most contend that the GCSE is responsible for the damage, it is unknown if the morbidity results from the underlying etiology or the GCSE. Regardless of the inducing stimulus, neuronal damage in animal models is evident following 30 to 60 minutes of GCSE, and most progress to develop epilepsy following a prolonged seizure. Interestingly, inhibiting the seizure-induced neuronal damage does not prevent the development of epilepsy, suggesting the seizures themselves may be harmful. It is hard to establish a relationship between GCSE and long-term outcomes because it is difficult to weigh the effects of seizure type, etiology, duration, concurrent physiologic events, and therapy or lack thereof. It has been shown that patients with a history of prolonged febrile seizures who later developed epilepsy share similar histopathologic changes (ie, hippocampal sclerosis) to those found in animal models of GCSE. In these cases, the period between the initial GCSE and the first epileptic seizure may be months to decades, suggesting a possible link between GCSE and the development of epilepsy. Importantly, studies of GCSE show that currently available antiseizure medications do not reproducibly prevent the development of epilepsy following prolonged seizures (ie, they are antiseizure medications and not antiepileptogenic).[13]

Patients who develop epilepsy following prolonged GCSE are less likely to experience remission of their seizures and may have decreased cognitive and memory function, mental impairment, or neurologic deficits when compared to those who develop epilepsy and subsequently have GCSE. Most studies have found that younger children, older patients, and those with preexisting epilepsy have a higher propensity for sequelae. Unless accompanied by an underlying neurologic abnormality, febrile SE is less likely to be associated with sequelae.

The overall worldwide case fatality rate of GCSE is 14.9%,[6] with the highest rate in those >60 years of age (24.9%), and in those with refractory GCSE (33.3%). Estimated mortality in the United States following GCSE ranges between 22,000 and 42,000 individuals per year, with rates lowest in children. The duration of seizure also impacts mortality. A 22% 1-year mortality rate has been seen for patients with refractory GCSE compared to 36% for those with super-refractory GCSE.[14] When compared with other populations, neonates have higher mortality and more neurologic sequelae.

Table 76-3 summarizes the etiology and corresponding GCSE mortality rates.[7,9] Interestingly, the mortality associated with many etiologies is significantly greater in adults than in children. Unresponsive patients may die from GCSE, but more frequently, they die from the acute illnesses that precipitated the GCSE. For example, patients with serious CNS structural changes (eg, hemorrhage and stroke) have a poorer prognosis than those with no structural lesion.

The outcome is affected by the time between the onset of GCSE and the initiation of treatment. Additionally, mortality significantly increases with increased seizure duration (eg, 2.6% for seizures 10-29 minutes, 19% for seizures lasting greater than 30 minutes, and 32% for seizures lasting greater than 60 minutes).[3,9] While mortality has decreased over the past decade, this probably reflects recognition of the need to initiate sequenced therapy using large doses of antiseizure medication as soon as possible.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Status Epilepticus

Symptoms

- Impaired consciousness (eg, lethargy to coma)
- Disorientation once GCSE is controlled
- Pain associated with injuries (eg, tongue lacerations, shoulder dislocations, back pain, myalgias, headache, and head trauma)

Early Signs

- Generalized convulsions
- Acute injuries or CNS insults that cause extensor or flexor posturing
- Hypothermia or fever suggestive of intercurrent illnesses (eg, sepsis or meningitis)
- Incontinence
- Normal blood pressure or hypotension and respiratory compromise

Late Signs

- Clinical seizures may or may not be apparent
- Pulmonary edema with respiratory failure
- Cardiac failure (dysrhythmias, arrest, and cardiogenic shock)
- Hypotension or hypertension
- Disseminated intravascular coagulation, multisystem organ failure
- Rhabdomyolysis
- Hyperpyrexia

Initial Laboratory Tests

- Complete blood count (CBC) with differential
- Serum chemistry profile (eg, electrolytes, calcium, magnesium, glucose, serum creatinine, alanine aminotransferase [ALT], and aspartate aminotransferase [AST])
- Urine toxicology/alcohol screen
- Blood cultures
- Arterial blood gas to assess for metabolic and respiratory acidosis, oxygenation
- Serum medication concentration if previous antiseizure medication(s) are suspected or known

Other Diagnostic Tests

- Spinal tap if CNS infection suspected
- EEG should be obtained on presentation and once clinical seizures are controlled
- CT with and without contrast
- MRI
- Radiograph if indicated to diagnose fractures

Accurate diagnosis requires observation, physical examination, laboratory assessment, EEG, and neurologic imaging. The nature and duration of the seizure should be obtained, but a diagnosis of GCSE should not be made until a seizure is observed by a clinician. Most patients have an altered consciousness, ranging from obtundation to marked lethargy and somnolence with pronounced eyes-open unresponsiveness and waxy rigidity. Motor features can include muscle contractions, extensor or flexor posturing, and spasms. Over time, the clinical manifestations become less apparent. This has significant ramifications as seizures appear to terminate without treatment or with ineffective therapy.

In addition to assessing language and cognitive abilities, the physical and neurological examinations should assess motor, sensory, and reflex abnormalities, pupillary response, asymmetry, and posturing. The patient should also be examined for secondary injuries (eg, tongue lacerations, shoulder dislocations, and head and facial trauma).

Laboratory tests are essential to the diagnosis of various etiologies. Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure all can cause seizures. A urine toxicology screen can help eliminate unhealthy substance use or overdose. Serum medication concentration(s) should be obtained for chronic antiseizure medications, as low concentrations can reflect partial adherence or rapid medication withdrawal. Although a baseline serum antiseizure medication concentration helps determine if a specific antiseizure medication loading dose is required, the time needed to perform the test makes this impractical. Assessment of other laboratory parameters that affect antiseizure medication dosing also can be helpful (eg, hematology and chemistries to include albumin, renal function, and hepatic function). An EEG is a valuable diagnostic tool, particularly in prolonged GCSE in whom clinically apparent seizures are not always evident. The initiation of antiseizure medication therapy should not be delayed while awaiting testing or results.

Once seizures have stopped, it is essential to determine if the patient is febrile or has a systemic or CNS infection. Many physiologic consequences of GCSE (eg, leukocytosis, pleocytosis, and hyperthermia) produce symptoms that can be confused with other conditions. If a CNS infection is suspected, a lumbar puncture should be performed, and empiric antibiotics started. If vascular, neoplastic, or infectious etiologies are suspected, computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained once the seizures are controlled.

TREATMENT

Various treatments are available for the management of GCSE. These range from rescue medications to abort the impending SE, to the use of pharmacologic and nonpharmacologic therapies for GCSE and refractory/resistant SE. The field has recently begun to shift terminology away from the disease focused terms (eg, antiepileptic medication) to the more function focused terms (eg, antiseizure medication). This shift is being done since many of these medications have no impact on the underlying disease, but in fact suppress seizures.[60]

Desired Outcomes

⑥ The short-term desired outcomes include: (a) immediate termination of all clinical and electrical seizure activity, (b) no clinically significant adverse effects, and (c) lack of recurrent seizure activity. The long-term outcomes involve minimizing or avoiding pharmacoresistant epilepsy and/or the development of neurologic sequelae that significantly impact the quality of life.

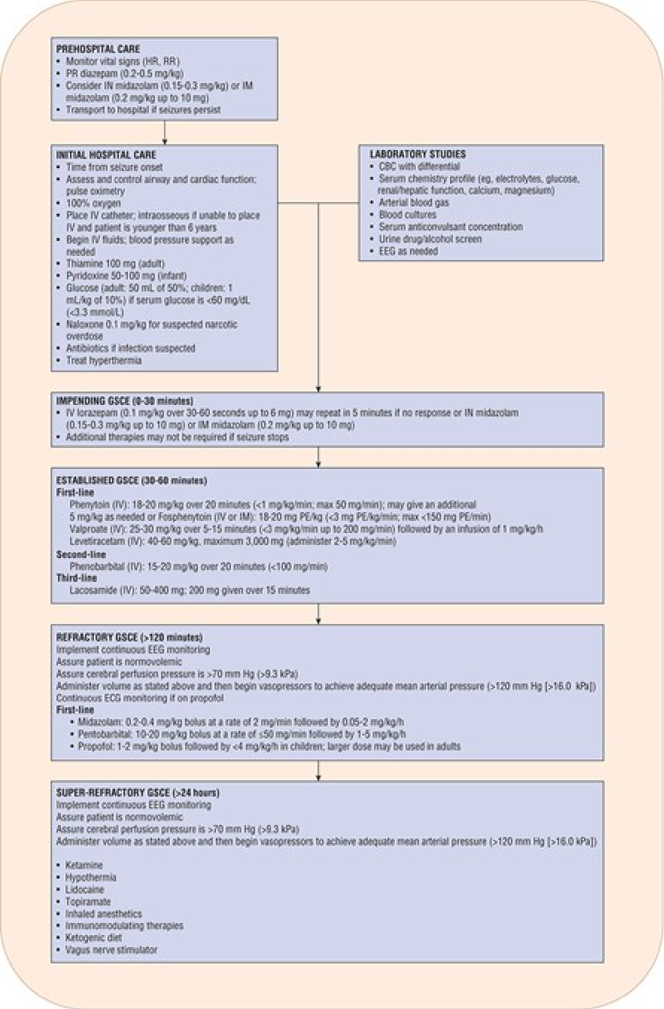
Nonpharmacologic Therapy

Stabilization Phase

Most of the treatment for GCSE consists of pharmacologic therapy in addition to supportive care. The time of seizure onset should be noted, and vital signs should be assessed. An adequate and protected airway should be established, ventilation should be maintained, and oxygen should be administered (Fig. 76-1). Intravenous access should be established, and hyperthermia, if present, should be aggressively treated (eg, rectal or IV acetaminophen and cooling blanket). Febrile GCSE is common in pediatrics, and normalization of body temperature helps minimize neurologic morbidity.

Figure 76-1

Algorithm for the treatment of GCSE. (BP, blood pressure; CBC, complete blood count; CI, continuous infusion; D12.5W, 12.5% Dextrose in water; D25W, 25% Dextrose in water; D50W, 50% Dextrose in water; EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; HR, heart rate; IN, intranasal; PE, phenytoin equivalents; PR, per rectum; RR, respiratory rate) *a* Because variability exists in dosing, monitor serum concentration.



PREHOSPITAL CARE
• Monitor vital signs (HR, RR)
• PR diazepam (0.2-0.5 mg/kg)
• Consider IN midazolam (0.15-0.3 mg/kg) or IM midazolam (0.2 mg/kg up to 10 mg)
• Transport to hospital if seizures persist
INITIAL HOSPITAL CARE
• Time from seizure onset
• Assess and control airway and cardiac function; pulse oximetry
• 100% oxygen
• Place IV catheter; intraosseous if unable to place IV and patient is younger than 6 years
• Begin IV fluids; blood pressure support as needed
• Thiamine 100 mg (adult)
• Pyridoxine 50-100 mg (infant)
• Glucose (adult: 50 mL of 50%; children: 1 mL/kg of 10%) if serum glucose is <60 mg/dL (<3.3 mmol/L)
• Naloxone 0.1 mg/kg for suspected narcotic overdose
• Antibiotics if infection suspected
• Treat hyperthermia
LABORATORY STUDIES
• CBC with differential
• Serum chemistry profile (eg, electrolytes, glucose, renal/hepatic function, calcium, magnesium)
• Arterial blood gas
• Blood cultures
• Serum anticonvulsant concentration
• Urine drug/alcohol screen
• EEG as needed
IMPENDING GSCE (0-30 minutes)
• IV lorazepam (0.1 mg/kg over 30-60 seconds up to 6 mg) may repeat in 5 minutes if no response or IN midazolam (0.15-0.3 mg/kg up to 10 mg) or IM midazolam (0.2 mg/kg up to 10 mg)
• Additional therapies may not be required if seizure stops
ESTABLISHED GSCE (30-60 minutes)
First-line
Phenytoin (IV): 18-20 mg/kg over 20 minutes (<1 mg/kg/min; max 50 mg/min); may give an additional 5 mg/kg as needed or Fosphenytoin (IV or IM): 18-20 mg PE/kg (<3 mg PE/kg/min; max <150 mg PE/min)
Valproate (IV): 25-30 mg/kg over 5-15 minutes (<3 mg/kg/min up to 200 mg/min) followed by an infusion of 1 mg/kg/h
Levetiracetam (IV): 40-60 mg/kg, maximum 3,000 mg (administer 2-5 mg/kg/min)
Second-line
Phenobarbital (IV): 15-20 mg/kg over 20 minutes (<100 mg/min)
Third-line
Lacosamide (IV): 50-400 mg; 200 mg given over 15 minutes
REFRACTORY GSCE (>120 minutes)
Implement continuous EEG monitoring
Assure patient is normovolemic
Assure cerebral perfusion pressure is >70 mm Hg (>9.3 kPa)
Administer volume as stated above and then begin vasopressors to achieve adequate mean arterial pressure (>120 mm Hg [>16.0 kPa])
Continuous ECG monitoring if on propofol
First-line
• Midazolam: 0.2-0.4 mg/kg bolus at a rate of 2 mg/min followed by 0.05-2 mg/kg/h
• Pentobarbital: 10-20 mg/kg bolus at a rate of ≤50 mg/min followed by 1-5 mg/kg/h
• Propofol: 1-2 mg/kg bolus followed by <4 mg/kg/h in children; larger dose may be used in adults
SUPER-REFRACTORY GSCE (>24 hours)
Implement continuous EEG monitoring
Assure patient is normovolemic
Assure cerebral perfusion pressure is >70 mm Hg (>9.3 kPa)
Administer volume as stated above and then begin vasopressors to achieve adequate mean arterial pressure (>120 mm Hg [>16.0 kPa])
• Ketamine
• Hypothermia
• Lidocaine
• Topiramate
• Inhaled anesthetics
• Immunomodulating therapies
• Ketogenic diet
• Vagus nerve stimulator

propofol. First-line treatment: Midazolam: 0.2-0.4 mg/kg bolus at a rate of 2 mg/min followed by 0.05-2 mg/kg/h; pentobarbital: 10-20 mg/kg bolus at a rate of _50 mg/min followed by 1-5 mg/kg/h or propofol: 1-2 mg/kg bolus followed by <4 mg/kg/h in children; larger dose may be used in adults. In super-refractory GSCE (>24 hours): Implement continuous EEG monitoring; assure patient is normovolemic; assure cerebral perfusion pressure is >70 mm Hg (9.3 kPa); administer volume as stated above and then begin vasopressors to achieve adequate mean arterial pressure (>120 mm Hg [16.0 kPa]); Give as required: ketamine, hypothermia support, lidocaine, topiramate, inhaled anesthetics, immunomodulating therapies, ketogenic diet or vagus nerve stimulator." class="contentFigures" />

Laboratory studies including serum glucose and electrolyte levels (including calcium and magnesium), complete blood count, and renal and hepatic function tests should be performed. Antiseizure medication serum concentration should be obtained as needed, and a urine toxicology screen should be performed if there is a suspicion of ingestion.

Although hypoglycemia rarely causes GCSE, adults and children (ages 2 years and older) with a blood glucose less than 60 mg/dL (3.3 mmol/L) should receive 50 mL of a 50% dextrose solution and 1 mL/kg of a 25% dextrose solution, respectively.[2] Because Wernicke's encephalopathy can develop in patients with an alcohol use disorder, adults should receive IV thiamine (100 mg) before glucose administration. Serum glucose concentration should be determined to assess the need for further supplementation. Children younger than 12 to 18 months of age should receive pyridoxine (Vitamin B_6) until metabolic causes are ruled out.

If an infection is suspected, blood cultures, lumbar puncture, and a urinalysis may be needed. Antibiotic administration does not need to wait until after the lumbar puncture if the patient is medically unstable. Patients with persistent GCSE should also have frequent arterial blood gas determinations to assess for metabolic acidosis, which should be treated with sodium bicarbonate if the pH is less than 7.2. Assisted ventilation can correct respiratory acidosis.

Because electrical seizures may persist in the absence of overt clinical motor manifestations, an EEG should be performed in patients who continue to have altered consciousness after clinical control of their seizures. Patients with persistent GCSE should also have continuous EEG monitoring.

Ketogenic Diet

A small number of reports have shown that an orally or intravenously administered ketogenic diet in a 4:1 ratio of fat to combined protein and carbohydrate can be used in severe cases of super-refractory SE.[15,16] Before initiating this diet, metabolic disorders as a possible etiology should be eliminated. Close monitoring of total daily fluid, ketosis, and potential complications is essential. If metabolic acidosis develops, treatment to maintain serum bicarbonate levels greater than 18 to 20 mEq/L (mmol/L) is recommended.[15]

Vagus Nerve Stimulation

Acute placement of a vagus nerve stimulator has been used in both pediatric and adult patients with refractory SE. Its use for refractory SE is not recommended currently, as grade D evidence suggests improvement in generalized refractory SE.[17]

Pharmacologic Therapy

Initial-Therapy Phase (5-20 Minutes)

When a seizure does not stop within 5 minutes, or when doubt exists regarding the diagnosis, patients should be treated as if they have GCSE (see Fig. 76-1), and initial therapies used. The benzodiazepines are the most common class of antiseizure medications used for GCSE initial treatment. Only two[18,19] and three[18,20,21] Class 1 studies have evaluated the benzodiazepines in children and adults, respectively.

⑦The benzodiazepines are considered effective initial therapy in most patients. Evidence-based guidelines recommend the initial use of IM midazolam, IV lorazepam, or IV diazepam (see Fig. 76-1) in adults and IV lorazepam or IV diazepam in children.[5] Intramuscular midazolam is preferred if IV access is not available; however, generally, one or two IV doses will terminate seizures within 2 to 3 minutes. All benzodiazepines are effective; therefore, preference is determined by pharmacokinetic differences, route of administration, pharmacoeconomics, adverse-effect profile, and current availability.

Diazepam is highly lipophilic with a large volume of distribution (1-2 L/kg). Although it distributes into the brain within seconds, it rapidly redistributes into fat, causing its CNS half-life to be less than 1 hour and its duration of effect to be less than 30 minutes. The rapid decrease in brain concentration, along with pharmacoresistance, can cause seizure recurrence; hence, a longer-acting antiseizure medication (eg, phenytoin, levetiracetam, or valproate) should be given immediately after diazepam. Table 76-4 outlines dosing.

Table 76-4

Dosing of Medications Used in the Initial and Established Treatment of GCSE

Medication (Route)	Brand name	Initial Dose (Maximum	Maintenance Dose	Comments

		Dose)		
Diazepam (IV)	Valium plus generic			
Adult		0.25 mg/kg[a,b,c] (20 mg)	Not used	Given IV at a rate not to exceed 5 mg/min
Pediatric		0.25-0.5 mg/kg[a,c] (20 mg)	Not used	
Fosphenytoin (IV)	Cerebyx plus generic			
Adult		20-25 mg PE/kg	4-5 mg PE/kg/day	Given IV at a rate not to exceed 150 mg PE/min in adults and 3 mg PE/kg/min in pediatric patients
Pediatric		20-25 mg PE/kg	5-10 mg PE/kg/day	
Lacosamide (IV)	Vimpat			
Adult		200-400 mg	200-400 mg/day, given twice a day	Administer IV over 15 minutes
Pediatric		6-10 mg/kg (400 mg)	6-12 mg/kg/day, given twice a day	
Levetiracetam (IV)	Keppra plus generics			
Adult		2,000-3,000 mg	1,000 mg thrice a day	Given IV over 5-10 minutes
Pediatric		40-60 mg/kg (3,000 mg)	40-60 mg/kg/day, given twice or thrice a day	
Lorazepam (IV)	Ativan plus generic			
Adult		4 mg[b,c] (6 mg)	Not used	Given IV at a rate not to exceed 2 mg/min in adult and pediatric patients

Pediatric		0.1 mg/kg[a,c] (6 mg)	Not used	
Midazolam (IV, IM)	Versed plus generic			
Adult		200 mcg/kg[a,d] (10 mg)	50-500 mcg/kg/hr[e]	Given IV at a rate 0.5-1 mg/min in adults and over 2-3 minutes in pediatric patients
Pediatric		150 mcg/kg[a,d] (10 mg)	60-120 mcg/kg/hr[e]	
Phenobarbital (IV)	Generic			
Adult		10-20 mg/kg[e]	1-4 mg/kg/day[e]	Given IV at a rate not to exceed 100 mg/min in adults and 30 mg/min in pediatric patients
Pediatric		15-20 mg/kg[e]	3-5 mg/kg/day[e]	
Phenytoin (IV)	Dilantin plus generic			
Adult		20-25 mg/kg[f]	4-5 mg/kg/day[e]	Given IV at a rate not to exceed 50 mg/min[g] in adults and 3 mg/kg/min (max 50 mg/min) in pediatric patients
Pediatric		20-25 mg/kg[f]	5-10 mg/kg/day[e]	
Valproate (IV)	Depacon plus generic			
Adult		15-30 mg/kg (3,000 mg)	1-4 mg/kg/hr[e]	Administer at 3 mg/kg/min; and follow by a continuous or intermittent infusion; larger doses may be required in those on hepatic enzyme inducers, monitor serum concentrations
Pediatric		20-25 mg/kg (3,000 mg)	1-4 mg/kg/hr[e], or give every 4-6 hours	

GCSE, generalized convulsive status epilepticus; PE, phenytoin equivalents.

[a] Doses can be repeated every 10 to 15 minutes until the maximum dosage is given.

[b] Initial doses in the older patients are 2 to 5 mg.

[c] Larger doses can be required if patients chronically on a benzodiazepine (eg, clonazepam).

[d] Can be given by the intramuscular, rectal, or buccal routes.

[e] Titrate dose as needed.

[f] Administer additional loading dose based on serum concentration.

[g] The rate should not exceed 25 mg/min in older patients and those with known atherosclerotic cardiovascular disease.

⑧ Most practitioners consider IV lorazepam to be the benzodiazepine of choice for initial therapy of GCSE. A Cochrane Database Review concluded that it is as effective and safer than diazepam in children.[21] Another Cochrane Database Review that included pediatric and adult data noted no difference in death, requirements for ventilator support, or adverse effects between the two agents; however, when compared to diazepam, there was a significantly lower risk of persistent seizures with lorazepam.[22]

Lorazepam is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, its minimal redistribution into fat results in a longer CNS duration of action, providing seizure protection for up to 24 hours. It also has a higher-affinity binding to the benzodiazepine receptor compared to diazepam.

Patients chronically on a benzodiazepine (eg, clobazam and clonazepam) might develop tolerance and require large doses. Diazepam and lorazepam contain propylene glycol, which can cause dysrhythmia and hypotension if administered too rapidly (Table 76-5). They also cause vein irritation; therefore, the parenteral product should be diluted with an equal volume of compatible diluent before administration. Because of slow and erratic absorption, standard parenteral formulations should not be given IM.

Table 76-5

Adverse Medication Reactions and Monitoring of Patients Receiving Medications for GCSE

Medication	Adverse Medication Reaction	Monitoring Parameters	Comments
Diazepam	Hypotension and cardiac arrhythmias	Vital signs and ECG during administration	Propylene glycol causes hypotension and cardiac arrhythmias when administered too rapidly; hypotension may occur with large doses
Fosphenytoin	Hypotension and cardiac arrhythmias; paresthesia, pruritus	Vital signs and ECG during administration	Hypotension is less than that noted with phenytoin, as this product does not contain propylene glycol; pruritus generally involves the face and groin areas, is dose and rate related, and subsides 5-10 minutes after infusion
Lacosamide	Prolonged PR interval	ECG	
Levetiracetam	Somnolence, behavioral abnormalities	Mental status	
Lidocaine	Fasciculations, visual		Occur at serum concentrations between 6 and 8 mg/L (26-34 µmol/L); seizures >8 mg/L (34 µmol/L)

	disturbances, tinnitus, seizures		
Lorazepam	Apnea, hypotension, bradycardia, cardiac arrest, respiratory depression, metabolic acidosis, and renal toxicity	Vital signs and ECG during administration; HCO_3 and serum creatinine; cumulative dose of propylene glycol	Accumulation of propylene glycol during prolong continuous infusions may cause acidosis
Midazolam	Apnea, hypotension, sedation	Vital signs and ECG	
Pentobarbital	Hypotension	Vital signs and ECG during administration	Rate of infusion should be slower or dopamine should be added if hypotension occurs
Phenytoin	Hypotension and cardiac arrhythmia; nystagmus	Vital signs and ECG during administration	Propylene glycol causes hypotension and cardiac arrhythmias when administered too rapidly. Large loading doses are generally not given to older individuals with preexisting cardiac disease or in critically ill patients with marginal blood pressure. The infusion rate should be slowed if the QT interval widens or if hypotension or arrhythmias develop; horizontal nystagmus suggests serum concentration above the reference range and toxicity; if a serum phenytoin concentration validates this, the dose should be decreased
Phenobarbital	Hypotension, respiratory, and CNS depression	Vital signs and mental status; EEG if used in anesthesia doses	Contains propylene glycol; if hypotension occurs, slow the rate of administration or begin dopamine; apnea and hypopnea can be more profound in patients treated initially with benzodiazepines
Propofol	Progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias	Vital signs, ECG, osmolar gap; EEG if used in anesthesia doses	Referred to as propofol-related infusion syndrome, which can be fatal
Topiramate	Metabolic acidosis	Acid-base status (serum bicarbonate)	Extremely rare

CNS, central nervous system; ECG, electrocardiogram; EEG, electroencephalogram.

Unfortunately, there is insufficient data comparing IV lorazepam to IV midazolam in GCSE. Midazolam has an extremely short half-life, and maintenance doses must be given by continuous infusion (see Table 76-4). Because of its increased solubility, midazolam has a more reliable IM absorption than either diazepam or lorazepam. A Class 1 study showed that IM midazolam, as first-line treatment given by medical personnel in the prehospital setting, was superior to IV lorazepam for cessation of seizures. This practice reduced intensive care unit (ICU) admission and subsequent hospitalization, with no differences in recurrent seizures or adverse effects.[18]

Intranasal (IN) midazolam and per rectum (PR) diazepam are increasingly used in out-of-hospital management and emergency department settings. However, evidenced-based guidelines indicate they and buccal midazolam are just probably effective.[5] Recent studies have focused on aborting impending SE via transmucosal benzodiazepine delivery (eg, PR, IN, and buccal) when IV and/or IM administration may be difficult or impossible (eg, home setting, extended care, and paramedic). Rectal absorption of diazepam is rapid but varies significantly (50%-100%) due to first-pass metabolism and can be challenging to administer at home. Buccal and sublingual routes bypass gastric and hepatic first-pass metabolism, but bioavailability can be incomplete as the medication is often swallowed. Buccal administration is easily accomplished, and the volume of fluid is small enough (eg, 2-5 mL) that aspiration is unlikely. While successful sublingual administration is unlikely due to muscular contractions of the jaw and clenching of teeth, non-IV midazolam is as effective as PR diazepam for termination of early SE in children.[23]

Intranasally administered midazolam readily crosses the nasal mucosa and the blood-brain barrier to produce a rapid rise in both serum and cerebrospinal fluid concentrations.[2] In fact, serum concentrations are comparable to those noted following IV injection. When compared to PR diazepam, all studies have concluded that IN midazolam results in higher serum concentrations, faster onset of action, more effective seizure control, and fewer adverse effects.[24] A commercially available, FDA-approved product for IN administration of midazolam became available in 2019, and a diazepam nasal spray product was approved in early 2020.[25-27]

Benzodiazepines are the first-line treatment for seizure emergencies; however, they are frequently underdosed, particularly in the out of hospital setting. A study including 1,170 benzodiazepine doses found that only 14.3% of midazolam and 23.9% of lorazepam doses met guideline recommendations.[28] Now that several benzodiazepine options are available for out-of-hospital treatment of seizure emergencies, it is critical to ensure that adequate doses are being prescribed and administered.

Guidelines also recommend IV phenobarbital as an alternative first-line agent in adults.[5] It is an effective and well-tolerated initial therapy in adults if benzodiazepines are not an option. Although evidence-based studies establish IV phenobarbital use, its slower administration rate than benzodiazepines relegates it to alternative initial therapy. Phenobarbital has biphasic distribution into body organs, and during phase I, it distributes into highly vascular organs but not the brain. Except for fat, phenobarbital distributes throughout the body during phase II; hence, lean body mass should be used in calculating doses in obese patients. Although the highest brain concentrations occur 12 to 60 minutes after an IV dose, seizures are controlled within minutes of the loading dose.[20]

The loading and maintenance dose for phenobarbital are given in Table 76-4. When necessary, larger loading doses (30 mg/kg) have been used in neonates without adverse effects. Phenobarbital exhibits first-order linear pharmacokinetics, and there is no maximum dose beyond which further doses are likely to be ineffective. For this reason, if the initial loading dose does not stop the seizures within 20 to 30 minutes, an option would be to give an additional dose (10-20 mg/kg) or move to anesthetic agents.[29] Once GCSE is controlled, start the maintenance dose within 12 to 24 hours. Although injectable phenobarbital contains propylene glycol, it can be given more rapidly than phenytoin (see Table 76-4). While it can be safely administered IM, its rate of absorption is too slow to be effective.[2]

Although rare, brief cardiorespiratory depression can necessitate assisted ventilation or require intubation (see Table 76-5). This is especially true if a benzodiazepine is used concomitantly with a barbiturate. The rate of respiratory depression in patients with GCSE who received benzodiazepines is lower than that reported in a similar population treated with placebo.[5] Importantly, there was no difference in cardiorespiratory adverse events in adults who are given either a benzodiazepine or phenobarbital.[20] Hypotension secondary to a reduction in vasomotor tone can occur following large doses of either a benzodiazepine or barbiturate.[2]

Second-Therapy Phase: Established GSCE (20-40 Minutes)

⑧⑨Second-phase antiseizure medications (eg, hydantoin, valproate, phenobarbital, levetiracetam, or lacosamide) may not be needed if seizures stop after administering initial therapies. The choice of which long-acting, second-line agent to give is controversial as there is no evidence to base a preferred option. When given, an agent should be administered immediately after a benzodiazepine. Dosing can be found in Table 76-4.

9 A hydantoin is one of three second-line agents that can be used when GCSE is unresponsive to benzodiazepine treatment or continues to occur after successful benzodiazepine treatment.[5] However, data supports a higher rate of seizure cessation and fewer adverse events with levetiracetam versus phenytoin.[30] When used by itself, phenytoin is inferior to lorazepam, phenobarbital, or diazepam plus phenytoin at stopping GCSE within 20 minutes of infusion.[20,31] While the most recent guidelines advocate for a hydantoin,[5] which are frequently used in practice, questions remain regarding if a hydantoin should be administered alone, in larger doses, or at all when seizures recur following benzodiazepine administration.

Phenytoin has a long half-life (20-36 hours) and causes less respiratory depression and less sedation than benzodiazepines or phenobarbital. However, it cannot be delivered rapidly enough to be considered a first-line single agent.[2] Injectable phenytoin should be diluted to greater than or equal to 5 mg/mL in normal saline; otherwise, microcrystals will precipitate if it is mixed in a glucose-containing solution. The vehicle (40% propylene glycol) can cause administration-related hypotension and cardiac arrhythmias (see Table 76-5). For this reason, the maximum rate of infusion is limited (see Table 76-4).

Table 76-4 includes suggested IV loading doses. A loading dose reduction is recommended for older patients, and a larger loading dose is required in obese individuals. If the patient has been on phenytoin prior to admission and the serum concentration is known, consider using this information in determining a loading dose. Although some advocate administering an additional 5 mg/kg dose in those with unresponsive GCSE, there is no evidence supporting this practice. Importantly this can cause concentrations to exceed the reference range and produce toxicity. In addition, because phenytoin has poor lipid solubility and enters the brain slowly, it can take up to 60 minutes before the pharmacodynamic effect is apparent. This delay is significant when considering administration of a second loading dose, as therapeutic serum concentrations, 10 to 20 mg/L (40-79 μmol/L), generally do not persist more than 24 hours; hence, maintenance doses (see Table 76-4) should be started within 12 to 24 hours of the loading dose.

Phenytoin has an alkaline pH, which may cause pain and burning during infusion. Phlebitis can occur during chronic infusion and tissue necrosis is likely on infiltration. Intramuscular administration of phenytoin is not recommended because absorption is delayed, erratic, and can crystallize in tissue. Although oral loading doses have been used in patients not actively seizing, it may take 4 to 12 hours before adequate serum concentrations are obtained. Thus, this practice is not recommended.

Fosphenytoin is considered by many to be the hydantoin of choice[5] as it is a water-soluble phosphate ester that has no known pharmacologic activity, and after IV or IM dosing is converted rapidly (7-15 minutes) and completely (100%) to phenytoin by blood and tissue phosphatases. The conversion delay was a concern initially; however, this time is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion. Since it does not contain propylene glycol, it is compatible with most common IV fluids. It should be dosed using phenytoin equivalents (PE), thereby obviating the need for interconversion between phenytoin and fosphenytoin. The loading dose and rates of administration of fosphenytoin can be found in Table 76-4. Because of delays in achieving adequate phenytoin serum concentrations, a loading dose should not be given IM unless IV access is impossible.

Fosphenytoin serum concentrations have no value, and therefore, serum phenytoin concentrations should be used for therapeutic medication monitoring with the desired serum concentration range being the same as phenytoin. However, fosphenytoin cross-reacts with some phenytoin immunoassays causing an overestimation of phenytoin concentration; hence, levels should not be obtained for at least 2 hours after IV, and 4 hours after IM administration.

Alternatively, the current guidelines also recommend a single dose of IV valproate or IV levetiracetam as acceptable first-line agents, if a benzodiazepine fails to control seizures after 20 minutes, or if seizures recur following a benzodiazepine and/or a hydantoin use.[5] Intravenous valproate and continuous infusion diazepam are comparable in GCSE.[32,33] One meta-analysis noted that valproate controlled refractory SE sooner than diazepam. However, there was no difference within 30 minutes of administration.[34] There was also no difference in control of GCSE between valproate and phenytoin.[27] A second meta-analysis noted that there is sufficient evidence to use valproate as first-line therapy in those with SE refractory to benzodiazepines.[35] Three randomized controlled trials have investigated the efficacy of levetiracetam[36-38] or valproate[36] versus fosphenytoin or phenytoin. One of these found that levetiracetam was not superior to phenytoin,[38] one concluded levetiracetam may be a reasonable alternative to phenytoin,[37] and one found that levetiracetam, fosphenytoin, and valproate all had similar safety and efficacy as a second-line GCSE agents.[36]

Several loading and continuous-infusion doses for valproate (see Table 76-4) have been used in adult and pediatric patients. Current guidelines recommend 40 mg/kg up to 3,000 mg as a single dose.[5] Although the manufacturer originally recommended IV valproate be given no faster than 20 mg/min, much faster rates have been studied (40 mg/min; 2-10 mg/kg/min) and are used for load dose administration. One study suggested the need to consider the effects of enzyme-inducing antiseizure medications when dosing and recommended that the continuous-infusion rate be determined by the presence of concurrent antiseizure medications (no inducers present, 1 mg/kg/hr; one or more inducers [eg, phenytoin and phenobarbital], 2 mg/kg/hr; and inducers and pentobarbital coma, 4 mg/kg/hr).[39] In general, IV valproate is well tolerated with no respiratory depression. Hemodynamic instability is extremely rare; however, vital signs should be monitored closely during the loading dose for hypotension.

Evidence for the use of IV levetiracetam is limited; however, evidence exists to support it as first-line therapy in those refractory to benzodiazepines.[40] Historically, it was used in cases of super-refractory SE, but it is being used earlier due to medication shortages that have made traditional medications unavailable. It is as effective as IV lorazepam in aborting seizures and preventing recurrence,[41-43] and compared to phenytoin is equally effective at terminating seizures and preventing recurrence at 24 hours.[43] Levetiracetam is not hepatically metabolized and is minimally protein bound, making medication interactions unlikely. Doses for IV levetiracetam are noted in Table 76-4 and are infused over about 5 minutes. Although guidelines recommend a maximum single dose of 4,500 mg,[5] most clinicians use 3,000 mg/day.

Despite being recommended as an alternative first-line agent for initial therapy, recent guidelines recommend phenobarbital as an alternative agent when a hydantoin, valproic acid, or levetiracetam is not available or has failed. Before moving to third-therapy phase, all agents noted in phase II should be administered as single doses, and not multiple mini-boluses, given at maximally tolerated doses.

Third-Therapy Phase: Refractory GCSE (40-60 Minutes)

⑩ When adequate doses of a benzodiazepine and a single dose of a second antiseizure medication (hydantoin, valproate, levetiracetam and/or barbiturate) fail, the condition is termed *refractory*.[5] After initial control, seizures can recur in 6% to 19% of patients. Approximately 10% to 15% of patients will develop refractory GCSE, and about 30% whose seizures are “clinically” controlled will have persistent electrical manifestations after antiseizure medication administration. When a patient develops refractory GCSE, an intense search should be performed for an acute or progressive cause.

While the goal is to stop electrical epileptiform activity, there is no consensus regarding the agent of choice, sequencing of therapy, or treatment of refractory GCSE.[44] Historically, one would recommend a repeat dose of a second-therapy phase; however, practitioners are increasingly using an anesthetic agent and not another traditional antiseizure medication due to the low probability that an additional traditional antiseizure medication will interrupt the established GCSE. There is a clear consensus that if a repeat dose of a traditional antiseizure medication fails, anesthetizing the patient to suppress cerebral ictal discharges should occur.[5] An anesthetic dose of midazolam, pentobarbital, or propofol may be indicated. Doses for these agents can be found in Table 76-5. Although it is likely that the patient is already being mechanically ventilated, intubation and respiratory support are mandatory during the use of anesthetic agents, along with continuous EEG monitoring.

While HLA-B*1502 has been associated with severe skin reactions in patients receiving phenytoin, this is applicable to chronic and not acute, single dose therapy. Recently, CYP2C variants that included CYP2C9*3, which reduce medication clearance, were identified as important genetic factors associated with phenytoin-related severe cutaneous adverse reactions.[45] Medication resistance factors have also been identified in surgically removed human epileptogenic tissue, as multimedication resistance proteins (P-glycoprotein) are localized to endothelial cells in brain capillaries and associated astroglia. Since multimedication resistance factors are localized to abnormal tissues, they appear to have little or no effect on systemic pharmacokinetic parameters of a medication. Still, they may affect local medication distribution within the target epileptogenic areas. If a role in refractory human epilepsy is confirmed, medication s that inhibit P-glycoprotein (eg, verapamil) may prove useful. However, the role of multimedication -resistant proteins in the treatment of seizure emergencies is not clear.

Benzodiazepines

During prolonged seizures, the number of γ_2 and $\beta_{2\text{-}3}$ subunits on the $GABA_A$ receptors decrease as the receptors move from the synaptic membrane into the cytoplasm. This move makes them functionally inactive, which may decrease the effectiveness of both endogenous GABA and GABA agonists resulting in time-dependent pharmacoresistance. Following GCSE that persists for more than 30 minutes, the relative potencies of benzodiazepines can be reduced up to 20-fold. For this reason, some believe that anesthetic doses of midazolam should be the first-line agent in refractory GCSE. If a benzodiazepine is used, it should always be combined with another medication that acts at a different site. Table 76-6 shows the loading and maintenance doses of midazolam.[32] Most patients respond to these doses within an hour. Although studies used seizure termination on EEG as the endpoint for success, EEG burst suppression is rarely achieved with the recommended doses of midazolam. Tachyphylaxis rapidly develops within 24 to 48 hours; hence, the dose is often increased to prevent seizure relapse.[2]

Table 76-6

Dosing of Medications Used to Treat Refractory or Super-Refractory GCSE

Medication (Brand Name)	Initial Dose (Maximum Dose)	Maintenance Dose	Comments
Ketamine (generics)			
Adult	1-4 mg	1-5 mg/kg/hr	
Pediatric	0.5-2 mg/kg	1-10 mg/kg/hr	
Lacosamide (Vimpat)			
Adult	200-400 mg	200 mg bid	Administer IV over 15 minutes, monitor serum concentrations
Pediatric	6-10 mg/kg (400 mg)	6-12 mg/kg/day, given twice a day	
Lidocaine (generics)			
Adult	50-100 mg	1.5-3.5 mg/kg/hr	Administer IV in ≤2 minutes
Pediatric	1 mg/kg (maximum 3-5 mg/kg in the first hour)	1.2-3 mg/kg/hr	
Midazolam (Versed plus generic)			
Adult	200 mcg/kg[a]	50-500 mcg/kg/hr[b]	Initial dose may be given IM; administer IV over 0.5-1 mg/min; continuous-infusion rate should be increased every 15 minutes in those who do not respond and should be guided by EEG response; development of tachyphylaxis can require frequent increases in dose; decrease dose by 1 mcg/kg/min every 2 hours once GCSE is controlled

Pediatric	150 mcg/kg[a]	60-120 mcg/kg/hr[b]	
Pentobarbital (generics)			
Adult	10-20 mg/kg	1-5 mg/kg/hr[b]	Over 1-2 hours, the rate of infusion should be slowed or dopamine should be added if hypotension occurs; gradually titrate dose upward until there is evidence of burst suppression on EEG (ie, isoelectric EEG) or prohibitive adverse effects occur. Twelve hours after a burst suppression is obtained, the rate should be titrated downward every 2-4 hours
Pediatric	15-20 mg/kg	1-5 mg/kg/hr[b]	
Propofol (Diprivan plus generic)			
Adult	2 mg/kg	5-10 mg/kg/hr[b]	Over 10 seconds in adults and 20-30 seconds in pediatric patients
Pediatric	3 mg/kg	2-4 mg/kg/hr[c]	
Topiramate (Topamax plus generic)			
Adult	300-500 mg	400-1,600 mg/day	Given orally in divided dose every 12 hours. Doses as large as 25 mg/kg/day for 2-5 days have been used in children. Monitor serum bicarbonate levels and serum concentrations
Pediatric	5-15 mg/kg (400 mg)	5-10 mg/kg/day, given thrice a day	

EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; IM, intramuscular; IV, intravenous.

[a] Doses can be repeated twice at 10-15 minute intervals until the maximum dosage is given.

[b] Titrate dose as needed.

[c] Generally recommended not to exceed a dose of 4 mg/kg/hr and a duration of 48 hours.

There is no specific protocol for tapering midazolam, but some suggest a seizure-free period of 24 to 48 hours before decreasing by 1 to 2 mcg/kg/min every 15 minutes.[2] Maintaining the patient's phenytoin and phenobarbital serum concentration(s) above 20 mg/L (79 µmol/L) and 40 mg/L (172 µmol/L), respectively, enhances successful discontinuation.

Because of midazolam's short half-life, patients can return to consciousness more rapidly compared to those receiving larger doses of more sedating antiseizure medications (eg, phenytoin and phenobarbital). Generally, continuous-infusion midazolam has been well tolerated, with few cases of hypotension and respiratory depression. If hypotension and poikilothermia occur, they can require supportive therapies. When adverse effects do occur, patients recover quickly; however, the use of large doses has caused a "midazolam infusion syndrome" in adults, which is characterized by delayed arousal (ie, hours to days) following midazolam discontinuation. This has tempered its use in adults, however its use has continued as an important agent in pediatrics. The availability of a pharmacological antidote for benzodiazepines, flumazenil, enhances the safe use of midazolam.

Pentobarbital

Use of a short-acting barbiturate is another anesthesia option (ie, pentobarbital or thiopental). These agents are preferred because they allow a more rapid reversal of coma. Although barbiturates are used frequently, there are no controlled trials to support this practice. In refractory GCSE, overall response rates are significantly greater in those treated with pentobarbital compared to midazolam or propofol.[46] The recurrence of seizures is also less frequent with pentobarbital and propofol. The reported mortality rates are similar for the three medications, but significant hypotension was more common with pentobarbital.

Several sources note that the initial loading dose of pentobarbital is 5 mg/kg; however, this dose is inadequate to achieve the serum concentrations (40 mg/L; 172 μmoL/L) necessary to induce an isoelectric EEG (see Table 76-6). Although the duration of barbiturate coma in most studies has been 2 to 3 days, it has been used safely for 53 days in an 18-year-old patient.[47] To avoid complications (eg, pneumonia and pulmonary edema), pentobarbital should be discontinued as soon as possible. The risk of seizure recurrence is minimized if other antiseizure medications are therapeutic before pentobarbital is withdrawn. Because pentobarbital is a potent hepatic enzyme inducer, higher maintenance doses of most concurrent antiseizure medications will be needed. Adverse medication reactions should be carefully monitored as de-induction occurs and antiseizure medication concentrations increase, which can occur up to a month after pentobarbital's discontinuation.

Propofol

Propofol is also a viable first-line alternative in phase III. It is extremely lipid soluble and has a large volume of distribution, a very rapid onset of action, and an extremely short half-life that promotes easy titration and rapid awakening on medication discontinuation. Although several studies have compared propofol and barbiturates, most studies were underpowered; however, its efficacy appears to be comparable to midazolam for refractory GCSE.[46,48] Propofol is given as a loading dose followed by a continuous infusion. The loading dose can be repeated every 3 to 5 minutes until the desired clinical response is obtained; however, the dose should be reduced once EEG burst suppression is achieved.

Adverse medication reactions can be found in Table 76-5. Prolonged infusions greater than 4 mg/kg/hr are associated with propofol-related infusion syndrome (PRIS), which may be more common in children and limits its use in this population.[49,50] Signs and symptoms of PRIS include progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias that are refractory to aggressive pharmacological treatments. It may occur with or without the presence of hepatomegaly, rhabdomyolysis, or lipemia. A retrospective case series of 41 patients with refractory GCSE noted that 10% had sudden unexplained cardiorespiratory arrests, and 35% had non-life-threatening features of PRIS.[50] Propofol may be proconvulsant in some patients as involuntary myoclonic movements have been reported.

Vital signs should be carefully monitored, and a continuous electrocardiogram (ECG) should be assessed for dysrhythmias. Guidelines proposing laboratory monitoring do not exist, but it would seem advisable to assess serum lactic acid, serum triglycerides, serum creatinine, creatine kinase, and hepatic enzymes in patients receiving doses larger than 4 mg/kg/hr and/or those receiving therapy for more than 48 hours.

The role and position of other antiseizure medications in refractory GCSE remains unclear, and shortages often complicate the selection of a second-phase antiseizure medication. The literature supports the use of lacosamide and topiramate's efficacy in refractory GCSE, although these data come from case reports or case series. Two reviews have noted there is insufficient evidence to support the routine use of lacosamide in benzodiazepine-resistant GCSE.[40,51,52] Topiramate has been given orally in adults and in children with GCSE and should be implemented at full therapeutic doses, divided three times a day (see Table 76-6).[2,53] To administer nasogastrically, the tablets should be crushed, mixed with water, and administered via syringe. The response tends to be delayed hours to days. Once seizures are controlled, the dose should be tapered to a standard age/weight–appropriate maintenance dosage. Aggressive implementation of large topiramate doses may cause hyperchloremic, non-anion gap metabolic acidosis due to inhibition of type II and IV carbonic anhydrase enzymes. This is not dose-related, as it has been noted following small doses, as well as overdoses. If metabolic acidosis occurs, treat with citrates to maintain serum bicarbonate of at least 20 mEq/L (mmol/L).[2]

Super-Refractory GCSE (>24 Hours)

Persistent GCSE or recurring seizures after anesthetic medications have failed are challenging. Therefore, agents with a broad range of pharmacologic mechanisms may be tried, such as ketamine, a noncompetitive antagonist of NMDA receptors. During prolonged seizures, the number and activity of GABA receptors gradually decrease; thus, the commonly used first-line and second-line antiseizure medications slowly fail. Simultaneously, the number and activity of glutamatergic NMDA receptors increase, often causing refractory status epilepticus (RSE). A summary of the findings regarding ketamine use in RSE was recently published.[2,54] Additionally, others have proposed an expert consensus-based treatment protocol for its use.[55] Overall, ketamine appears to be a reasonable agent to consider in refractory GCSE that has failed general anesthesia, especially in those with cardiac instability. Ketamine doses can be found in Table 76-6. An advantage of ketamine is its ability to maintain arterial blood pressure, pulse rate, and cardiac output. Adverse events noted include hallucinations upon awakening, increased salivation, and increased intraocular and intracranial pressure.

Currently, weak evidence supports the use of lidocaine in super-refractory GCSE, although clinically it has been used when other agents fail.[56] When administered intravenously (see Table 76-6) it has a rapid onset of action. The therapeutic reference range for GCSE has not been established. However, the reference serum concentration range for the antiarrhythmic effects of lidocaine is 2 to 6 mg/L (8.5-26 μmol/L). Serum lidocaine concentrations and ECG should be monitored to avoid medication accumulation and toxicity (see Table 76-5).

Inhaled anesthetics are currently not used until other approaches fail. A few studies have used inhaled anesthetics (particularly isoflurane) for the treatment of refractory SE.[15,57] Halothane, isoflurane, and other inhaled anesthetics can produce EEG suppression. These agents are challenging to deliver outside the operating room and require an anesthesiologist; however, they offer no proven advantages over traditional antiseizure medications (eg, barbiturate coma or continuous-infusion benzodiazepine), and can increase intracranial pressure. If used, dosing is titrated to obtain EEG burst suppression, and although required concentrations are variable, isoflurane generally stops seizure at concentrations of 0.5% to 3%. It is important to note that these concentrations are not ordinarily associated with hemodynamic effects; however, isoflurane can induce hypotension. Therefore, close hemodynamic monitoring is necessary, and the administration of isotonic fluids and vasopressors as needed.

Data that suggest the development of super-refractory GCSE may be due to antibodies directed against the voltage-gated potassium channels and the NMDA receptor. However, the use of immunomodulating therapies (eg, corticosteroids and IV immune globulin) is based solely upon animal data.[15] Additionally, mounting evidence suggests that inflammation plays a role in epileptogenesis, particularly the activation of select inflammatory signaling pathways (eg, interleukin-1 receptor/toll-like receptor [IL-1R/TLR]). Steroids may also decrease blood-brain barrier opening and reverse GABAergic inhibition and affect NMDA and voltage-gated potassium channels. Although little evidence supports the use of steroids, in the absence of contraindications, a trial of large doses of steroids that IVIG follows should be considered. Typically, patients are given methylprednisolone 15 mg/kg/day every 6 hours, up to 1 g/day, for 3 days. Patients who respond should continue long-term steroids, IV immunoglobulins, and other immunomodulatory agents such as cyclophosphamide or rituximab.[58]

Controlled mild hypothermia reduces excitatory transmission, epileptic discharges, reduces brain edema, cerebral metabolic rate, oxygen utilization, and ATP consumption. Few studies have assessed the efficacy or safety of hypothermia in refractory GCSE and a meta-analysis suggested that only level D evidence supports the use of hypothermia in refractory SE.[59] Despite an absence of medical evidence, there has been a resurgence in the use of hypothermia, especially its use early on in super-refractory GCSE. When used, a core body temperature of about 32°C to 34°C is targeted for at least 24 to 48 hours. It may or may not be given in combination with barbiturate anesthetics,[15] but is often used concurrently with ketamine. Cardiovascular and coagulation parameters, biochemistry and acid-base balance, and serum lactate should all be monitored. Hypothermia may significantly reduce the clearance of several medication s, including anesthetics and antiseizure medications, resulting in a need for monitoring of serum concentrations.[2]

EVALUATION OF THERAPEUTIC OUTCOMES

Initial success for GCSE is defined as termination of all clinical and electrical seizure activity, but ultimate success is measured by the patient's subsequent quality of life. The morbidity and mortality associated with GCSE are primarily affected by the underlying etiology; however, morbidity and mortality can be minimized by the rapid implementation of a rational therapeutic plan. The EEG is a vital tool that not only allows practitioners to determine when abnormal electrical activity has been aborted but also can assist in determining which antiseizure medication was effective. Because many antiseizure medications affect the cardiorespiratory system, vital signs (eg, heart rate, respiratory rate, and blood pressure) must be monitored during medication loading and infusion. Finally, the infusion site must be assessed for any evidence of infiltration before and during the administration of phenytoin. Information regarding the patient's past medical and medication history and imaging studies (eg, MRI) can also help determine if there is a defined etiology for the original episode of GCSE. This information can then be used to guide future medication therapy and help determine if the patient is at risk for a poor outcome.

CONCLUSION

GCSE is a medical emergency that requires all healthcare professionals to be knowledgeable about the phases of the disorder, the therapies that align with each phase, and secondary complications that need to be addressed. This requires clinicians to have a working knowledge of the Patient Care Process used for status epilepticus and understand what evidence-based information exists to select therapies. Additionally, knowing and identifying any provoking factors and/or various etiologies important in prevention and treatment is an integral part of care. Finally, it is also essential that outpatient therapies be aggressively used to abort impending SE.

ABBREVIATIONS

AMPA	α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate
ASM	antiseizure medication
CNS	central nervous system
CT	computed tomography
ECG	electrocardiogram
EEG	electroencephalogram, electroencephalography
GABA	γ-aminobutyric acid
GCSE	generalized convulsive status epilepticus
ICU	intensive care unit
IL-1R/TLR	interleukin-1 receptor/toll-like receptor
ILAE	International League Against Epilepsy
IM	intramuscular
IN	intranasal
IV	intravenous
MRI	magnetic resonance imaging
NCSE	nonconvulsive status epilepticus
NMDA	*N*-methyl-D-aspartate
PE	phenytoin equivalents
PRIS	propofol-related infusion syndrome
RSE	refractory status epilepticus
SE	status epilepticus

SELF-ASSESSMENT QUESTIONS

1. An 8-year-old has fallen to the ground and began twitching and jerking both arms and legs. The jerking lasted for about 2 to 3 minutes, after which he would wake up, but have no memory of the event and began to seize again. When the emergency medical technicians (EMTs) arrive at the home the child is still seizing. Which medication should the EMTs administer?

A. IM diazepam

B. IM phenytoin

C. IV lorazepam

D. IN phenobarbital

2. A 32-year-old arrives in the emergency department due to a generalized convulsive seizure. They were given a single 0.1 mg/kg dose of lorazepam in the ED but continues to seize. The duration of seizures is now 15 minutes. Which would you recommend?

A. Administer an IV loading dose of phenobarbital

B. Administer an IM dose of diazepam instead of lorazepam

C. Administer a second IV dose of the lorazepam

D. Do not give additional antiseizure medications until an EEG is performed

3. Which is a risk factor for poor outcome in a patient with GCSE?

A. Seizures persisting for more than 60 minutes

B. Adults <60 years of age

C. Patients without any CNS structural abnormalities

D. Febrile seizure

4. Which is *true* regarding IV fosphenytoin and IV phenytoin?

A. Phenytoin causes pruritus, whereas fosphenytoin does not.

B. Fosphenytoin does not cause arrhythmias, whereas phenytoin does.

C. A phenytoin serum concentration should be drawn 1 hour after IV loading dose of phenytoin; whereas a phenytoin serum concentration should be drawn 2 hours after an IV dose of fosphenytoin.

D. The rate of administration is the same for both drugs.

5. Which is *true* regarding diazepam and lorazepam?

A. Lorazepam has a more rapid onset than diazepam.

B. Lorazepam has a longer duration of action than diazepam.

C. Diazepam is not metabolized while lorazepam is metabolized.

D. Diazepam can be given IM, while lorazepam can only be given IV.

6. Which is *true* regarding the administration of propofol?

A. Prolonged infusions greater than 4 mg/kg/hr have been associated with propofol-related infusion syndrome in pediatric patients.

B. The long half-life enables the drug to be given intermittently in patients with refractory GCSE.

C. It should be used in phase II (established GCSE).

D. It may cause tachyarrhythmias.

7. A 57-year-old (85 kg) patient with a history of complex partial seizures (2 per month) presents to the ED because of a “long” seizure at home that was at least partly witnessed by his partner. They were given a single dose of lorazepam and is now seizure free. Theychronically have received Carbatrol 600 mg BID. All chemistries, including liver function test and CBC, are normal. What would you recommend as part of this patient’s workup?

A. STAT EEG

B. STAT MRI

C. Carbamazepine serum concentration

D. Urine drug screen

8. Tachyphylaxis is most commonly associated with which medication?

A. Midazolam

B. Ketamine

C. Propofol

D. Phenobarbital

9. Which should *not* be administered IM in GCSE?

A. Midazolam

B. Phenobarbital

C. Diazepam

D. Fosphenytoin

10. Phenytoin, phenobarbital, diazepam, and lorazepam all contain propylene glycol. Which is *not* a sign of propylene glycol toxicity?

A. Dysrhythmia

B. Hypotension

C. Metabolic acidosis

D. Hepatic failure

11. Which is *true* regarding IN midazolam?

A. It should not be used in infants.

B. The entire dose should be administered in the same nostril.

C. The syringe used to administer the IN midazolam should be overfilled by 0.1 mL.

D. Effectiveness is the same whether or not an atomizer is used.

12. A 2-year-old child is transported to the emergency department following a generalized tonic-clonic seizure. The parent states that the child does not have epilepsy, but does take Flonase, Singular, Theo-Dur, and albuterol prn. They are afebrile. As part of the initial workup, which test would be most helpful in evaluating the seizure etiology?

A. Blood electrolytes

B. Liver function test

C. STAT EEG

D. Serum theophylline concentration

13. 75 mg of fosphenytoin is equivalent to how many milligrams of phenytoin?

A. 50 mg PE

B. 75 mg PE

C. 100 mg PE

D. 125 mg PE

14. An adult patient is admitted to the ICU for persistent GCSE. To date, the patient has received appropriate doses of 0.1 mg/kg lorazepam and 20 mg/kg PE fosphenytoin (1,500 mg PE), but continues to seize. Which IV medication would be best to recommend?

A. IV lorazepam

B. IV levetiracetam

C. CI propofol

D. Hypothermia

15. An EMT contacts you regarding the storage of antiseizure medications used during transport. Which must be refrigerated?

A. Midazolam

B. Fosphenytoin

C. Valproate

D. Phenobarbital

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The Evidence-based guidelines recommend the initial use of IM midazolam, IV lorazepam, or IV diazepam in adults and the use of IV lorazepam or IV diazepam in children. IM midazolam is preferred if IV access is not available (see Fig. 76-1 and section “Initial Therapy Phase”).
2. **C.** Since seizures have persisted for <20 minutes, the patient is still in the initial phase of SE. At this time, the guidelines recommend that the patient received a second dose of lorazepam (see Fig. 76-1 and section “Initial Therapy Phase”).
3. **A.** Mortality significantly increases with increased seizure duration (eg, 2.6% for seizures 10 to 29 minutes, 19% for seizures lasting greater than 30 minutes, and 32% for seizures lasting greater than 60 minutes) (see section “Morbidity and Mortality”).
4. **C.** A phenytoin serum concentration should be drawn 1 hour after the end of an IV loading phenytoin; whereas a phenytoin serum concentration should be drawn 2 hours after the end of an IV dose of fosphenytoin (see section “Second-Therapy Phase: Established GCSE”).
5. **B.** Lorazepam is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, its minimal redistribution into fat results in a longer duration of action in the CNS, which can provide seizure protection for up to 24 hours. It also has a higher-affinity binding to the benzodiazepine receptor than diazepam (see section “Initial-Therapy Phase”).
6. **A.** Prolonged infusions greater than 4 mg/kg/hr have been associated with propofol-related infusion syndrome (PRIS). Signs and symptoms of PRIS include progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias that are refractory to aggressive pharmacological treatments and occur primarily in pediatric patients. It may occur with or without the presence of hepatomegaly, rhabdomyolysis, or lipemia. It is more common in children, and this limits the use of this agent in the pediatric population (see Table 76-5 and section “Third-Therapy Phase: Refractory GCSE”).
7. **C.** Because seizures stopped after a single dose of lorazepam, no additional initial antiseizure medication is warranted. Given the patient has been already diagnosed with epilepsy, there is no need for an EEG, MRI, or urine toxicology screen. One of the most frequent precipitating events for SE in adults is low antiseizure medication concentrations. A serum carbamazepine concentration will allow assessment of patient adherence to chronic therapy and influence on current presentation, requirement for a change in dosage, and need for patient education (see Table 76-3 and Patient Care Process for Status Epilepticus).
8. **A.** During prolonged seizures, the number of γ_2 and $\beta_{2\text{-}3}$ subunits on the GABAA receptors decrease as the receptors move from the synaptic membrane into the cytoplasm where they are functionally inactive. These modifications may decrease the effectiveness of both endogenous GABA and GABA agonists and result in time-dependent pharmacoresistance. Following GCSE that persist for more than 30 minutes, the relative potencies of benzodiazepines can be reduced up to 20-fold. Tachyphylaxis to midazolam rapidly develops within 24 to 48 hours; hence, the dose is often increased to prevent seizure relapse (see section “Third-Therapy Phase: Refractory GCSE” and its subsection “Benzodiazepine”).
9. **C.** Because of slow and erratic absorption, diazepam should not be given IM. In patients without an established IV site, IM midazolam is the preferred benzodiazepine for intramuscular administration (see Table 76-4 and section “Initial Therapy Phase”).
10. **D.** Continuous infusion of medications that contain propylene glycol has been known to cause hyperosmolality, increased anion gap and osmolar gap metabolic acidosis (due to lactic acidosis), central nervous system depression, cardiac arrhythmias, hypotension, respiratory arrest, hemolysis, and acute renal failure. This most frequently occurs in patients with renal dysfunction, who were receiving prolonged infusions of medications that contain propylene glycol (see Table 76-5).
11. **C.** It is imperative to account for medication that will remain in the dead space within the atomizer tip by overfilling the syringe with 0.1 mL of medication (see section “Initial-Therapy Phase”).

12. **D.** Many medications are known to cause seizures if used in excess. Theophylline is such a medication. Whenever a patient without a history of epilepsy presents with a seizure, it is imperative that the clinician rule out medications as an etiology (see Patient Care Process box).

13. **B.** The dose, concentration, and infusion rates for fosphenytoin are expressed as phenytoin equivalents (PE); fosphenytoin should *always* be prescribed and dispensed in PE; fosphenytoin 1.5 mg is equivalent to phenytoin 1 mg and is referred to as 1 mg PE (see Fig. 76-1 and Table 76-4).

14. **C.** When adequate doses of a benzodiazepine and a single dose of a second antiseizure medication(hydantoin, valproate, levetiracetam, and/or barbiturate) have failed, the condition is termed *refractory*. At this time, the goal is to stop electrical epileptiform activity as soon as possible, which could be best accomplished by anesthetizing the patient. Anesthetic dose of midazolam, pentobarbital, or propofol would be indicated (see Fig. 76-1 and section "Third-Therapy Phase: Refractory GCSE").

15. **B.** Store intact vials refrigerated at 2°C to 8°C (36°F-46°F). Do not store at room temperature for more than 48 hours. After opening, discard any unused solution in vials (see the Beyond the Book activity).

Chapter 77: Acute Management of the Brain Injury Patient

Bradley A. Boucher; G. Christopher Wood

KEY CONCEPTS

KEY CONCEPTS

① Cerebral ischemia is the key pathophysiologic event that triggers secondary neuronal injury following severe traumatic brain injury (TBI). Intracellular calcium accumulation is postulated to be a central pathophysiologic process in amplifying and perpetuating secondary neuronal injury via inhibition of cellular respiration and enzyme activation.

② *Guidelines for the Management of Severe Brain Injury*, 4th edition, published by the Brain Trauma Foundation (BTF)/American Association of Neurological Surgeons (AANS), serve as the foundation on which clinical decisions in managing adult neurotrauma patients are based; comparable guidelines for infants, children, and adolescents have also been published.

③ Correcting and preventing early hypotension (systolic blood pressure [SBP] less than 100-110 mm Hg depending on age) with an SBP goal of 120 to 140 mm Hg and reversal of hypoxemia are primary goals during the initial resuscitative and intensive care of patients with severe TBI.

④ Nonpharmacologic management of intracranial hypertension includes raising the head of the bed 30°, and ventricular drainage if an extraventricular drain (EVD) is present.

⑤ The principal monitoring parameter for patients with severe TBI within the intensive care environment is increased intracranial pressure (ICP). Cerebral perfusion pressure (CPP) is also a critical monitoring parameter and should be maintained between 60 and 70 mm Hg (8.0 and 9.3 kPa) (greater than 40 and 50 mm Hg [5.3 and 6.7 kPa] in pediatric patients) through the use of fluids, vasopressors, and/or ICP normalization therapy.

⑥ Nonspecific pharmacologic management of intracranial hypertension should include analgesics, sedatives, and antipyretics; paralytics may be advantageous under selected circumstances.

⑦ Specific pharmacologic management of intracranial hypertension includes mannitol, hypertonic saline, furosemide, and high-dose pentobarbital. Neither routine use of corticosteroids nor aggressive hyperventilation (ie, $PaCO_2$ less than 25 mm Hg [3.3 kPa]) should be used in the management of intracranial hypertension.

⑧ Numerous investigational strategies targeted at limiting injury and/or stimulating axonal repair following severe TBI have been employed; however, no proven therapeutic benefits have been identified.

⑨ Use of phenytoin (alternatively levetiracetam) for the prophylaxis of posttraumatic seizures generally should be discontinued after 7 days if no seizures are observed.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Overview of Traumatic Brain Injury (TBI)” (https://www.youtube.com/watch?v=T0WBMM7WKL4) presented by Dr. Christopher Wolf and moderated by Brent Ghan at the University of Missouri School of the Health Professions. This 7.5-minute video provides a general overview of human brain anatomy and physiology and a succinct introduction to the more detailed pathophysiology outlined in the chapter and a context for understanding TBI pharmacologic and nonpharmacologic management. This includes TBI pathophysiology including cerebral contusions, diffuse axonal injury, secondary brain injury, in addition to TBI recovery.

INTRODUCTION

TBI is one of the leading causes of death and disability in the United States.[1] A focus on TBI prevention, improved acute care, and rehabilitation remain national priorities. This chapter summarizes TBI epidemiology and pathophysiology, and highlights the major guidelines and systematic literature reviews pertaining to the severe TBI management.

EPIDEMIOLOGY

Approximately 2.87 million persons sustain a TBI each year in the United States equating to one occurring nearly every 11 seconds.[1] Among these individuals, over 288,000 require hospital admission, and over 56,000 die annually.[1] Importantly, an estimated 5.3 million Americans live with disabilities resulting from their TBI, highlighting the enormous physical and emotional toll of this healthcare problem.[2] The economic effects of acute neurotrauma are also enormous, with estimates of direct and indirect spending on patients requiring hospitalization reaching $76.5 billion in the United States in 2010.[2] Economic costs to society from lost productivity are also massive, especially considering the young age of many patients with TBI.[2] Falls are the leading cause of unintentional TBI (48%), while TBI-related hospitalizations and deaths vary based on age.[1,2] For example, death rates from TBI after a fall are highest in patients aged 65 years or older while motor vehicle crashes are the leading cause of death in persons aged 15 to 34 years and adults over 75 years.[1]

PRIMARY AND SECONDARY BRAIN INJURY PATHOPHYSIOLOGY

The neurologic sequelae of brain trauma can occur instantaneously as a consequence of the primary injury or can result from secondary injuries that follow within minutes, hours, or days after the initial injury.[3] Primary injury involves the external transfer of kinetic energy to various structural components of the brain (eg, neurons, nerve synapses, glial cells, axons, and cerebral blood vessels). The biomechanical forces responsible for primary brain injury can be classified broadly as contact (eg, blunt-object blow, penetrating-missile injuries) and acceleration/deceleration (eg, instantaneous brain movements following motor vehicle accidents).[3] Contact forces to the head commonly result in skull fractures, brain contusions, and/or hemorrhages. Primary brain injuries are categorized further as focal (eg, contusions, hematomas) or diffuse,[3,4] with the latter usually being associated with shearing or stretch forces, which primarily affect axons within the brain (ie, diffuse axonal injury).[4] The type of primary injury (ie, focal vs diffuse) is a major factor as to which of the secondary injury mechanisms discussed below will predominate following a TBI; however, many patients, especially those involved in high-speed accidents, sustain both types of injury.[3,4]

① A complex sequence of pathophysiologic events precipitated by primary brain injury may seriously disrupt the normal central nervous system (CNS) balance between oxygen supply and demand resulting in a metabolic crisis.[5,6] Hypotension during the early posttraumatic period is a major contributor to this imbalance and a primary determinant of outcome. The end result of this imbalance is cerebral ischemia, the key pathophysiologic event triggering secondary injury.[5] Figure 77-1 is a simplified schematic of the processes that constitute secondary brain injury and their various interrelationships. The brain is particularly susceptible to ischemia because of its normally high resting energy requirement and its limited capacity to store oxygen, glucose, and adenosine triphosphate (ATP). These phenomena can result in imbalances in cerebral oxygen delivery (CDO_2) and cerebral metabolic rate of oxygen consumption ($CMRO_2$), processes that are closely autoregulated under normal circumstances.[5] Factors that can diminish cerebral oxygen supply following brain injury include cerebral edema, expanding mass lesions (eg, epidural, subdural, and intracerebral hematomas), cerebral vasospasm, and loss of vasoregulatory control. Vasogenic cerebral edema can develop as a consequence of cerebral capillary endothelial damage and disruption of the blood–brain barrier.[6] Cytotoxic cerebral edema is a consequence of loss of cell wall integrity that accompanies ischemia or hypoxia with accumulation of lactic acid secondary to anaerobic metabolism.[7] With cytotoxic and vasogenic edema comes expansion of the intracellular and extracellular fluid spaces, respectively. Increased intracranial pressure (ICP) is the most detrimental consequence of cerebral edema formation, which occurs as the brain tissue volume increases within the nondistensible skull. A significant ICP increase may further compromise cerebral blood flow (CBF) and extend cytotoxic edema. Hence, increased ICP can be self-perpetuating unless reversed. Hypoxemia can further exacerbate local decreases in cerebral oxygen supply following acute respiratory failure and systemic hypotension. Metabolic demand also can increase following neurotrauma secondary to seizures, agitation, and temperature elevation.

FIGURE 77-1

Schematic illustration of the cascade of biochemical events proposed to occur following severe neurotrauma (secondary brain injury). (Ca, calcium; Cl, chloride; CNS, central nervous system; K, potassium; Mg, magnesium; Na, sodium; PMN, polymorphonucleocyte; PGH_2, prostaglandin H_2; PGG_2, prostaglandin PGG_2; PGI_2, prostaglandin PGI_2.)

Two distinctive end points along the spectrum of secondary neuronal injury are: (a) energy-independent cellular necrosis characterized by membrane cell lysis, edema, and inflammation, and (b) energy-independent apoptosis leading to cell shrinkage and cell membrane dissolution.[7] Apoptosis, which is also known as programmed cell death, requires a cascade of intracellular events for cell death completion with ionic homeostasis loss being postulated as a key event in fostering secondary brain injury following cerebral ischemia.[7] In this process, cellular influx of sodium, chloride, magnesium, and water occurs with a corresponding efflux of potassium secondary to cytotoxic edema and Na^+-K^+-ATPase pump dysfunction. Calcium influx into the presynaptic terminal ends of damaged neurons is mediated by N-type voltage-sensitive calcium channels and is postulated to stimulate excessive release of the excitatory amines glutamate and aspartate from the affected neurons. These amines then accumulate in the neuronal synaptic cleft in the presence of cellular energy failure, resulting in ongoing stimulation of postsynaptic cells, which extend neurotoxicity and cell death. The influx of calcium and additional sodium is stimulated by activation of ionophore receptors including the *N*-methyl-D-aspartate (NMDA) receptor.[7] Calcium influx and its intracellular accumulation initiate a number of events that amplify and perpetuate secondary neuronal injury as well as mitochondrial dysfunction, which further inhibits cellular respiration, a process already affected by ischemic and/or hypoxic insults.[5,7] A second major deleterious effect of calcium is activation of autodestructive enzymes, including phospholipases, endonucleases, and proteases, such as the caspase family of enzymes.[7] The effect of phospholipase A_2 stimulation includes formation of several arachidonic acid metabolites derived from membrane lipids (eg, thromboxane A_2, prostaglandins, and leukotrienes) that facilitate lipid peroxidation and reactive oxygen species formation.[5,7] This event occurs early after injury (eg, before hospitalization), which may limit the effectiveness of exogenously administered antioxidants. Cell-mediated injury involving inflammatory mediators (eg, proinflammatory cytokines) and nitric oxide activation is another possible mechanism involved in secondary neuronal injury,[6,7] implicating polymorphonuclear neutrophils, platelets, endothelial cells, and macrophages. However, activation of some inflammatory mediators may actually be beneficial, such that the relative balance of the mediators rather than absolute concentrations may be the most significant pathophysiologic factor following TBI. Stimulation of platelet aggregation, vasodilation, and vasoconstriction also may occur.[5]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: ACUTE BRAIN INJURY

General

- Level of consciousness on admission ranges from completely unresponsive to awake and alert (ie, Glasgow Coma Scale 3-15 [Table 77-1]).

Symptoms

- Posttraumatic amnesia (eg, greater than 1 hour), increasing dizziness, a moderate-to-severe headache, nausea/vomiting, limb weakness, or paresthesia may indicate more severe injury.

Signs

- Cerebrospinal fluid (CSF) otorrhea or rhinorrhea, seizures, or unequal or unreactive pupils may indicate more severe injury.
- A rapid deterioration in mental status strongly suggests the presence of an expanding lesion within the skull.
- Severe TBI may be accompanied by significant alterations or instability in vital signs, including abnormal breathing patterns (eg, apnea, Cheyne–Stokes respiration, tachypnea), hypertension, or bradycardia.

Laboratory Tests

- Arterial blood gases (ABGs) indicating hypoxia (ie, decreased PaO_2) or hypercapnia (ie, increased $PaCO_2$) may indicate compromised ventilation.
- Blood ethanol concentration and/or urine toxicology results indicates that substance intoxication may be affecting the patient's mental status in addition to the TBI.
- Electrolyte disturbances can cause alterations in mental status, and their effects may interfere with assessment of the patient's neurological status.

Other Diagnostic Tests

- CT scan of the head is an important diagnostic tool for detecting the presence of mass lesions and structural signs of edema (eg, midline shift, compressed ventricles).

The Glasgow Coma Scale (GCS) was designed nearly 50 years ago and is still the most widely used system to grade the arousal and functional capacity of the cerebral cortex,[3] as it defines the level of consciousness according to eye opening, motor response, and verbal response (Table 77-1). A GCS score of 15 corresponds to a normal neurologic examination based on eye, motor, and verbal responses. Scores from 3 to 8 correspond to severe brain injury, while scores from 9 to 12 and 13 to 15 is consistent with moderate, and mild or minor brain injury, respectively.[3] Always consider the impact of ethanol or substance intoxication, hypotension, hypoxia, postictal state, hypoglycemia, electrolyte imbalances, or hypothermia on altering the neurologic examination when administering this scale. Opiates, sedatives, and neuromuscular blockers should not be administered until the initial examination is complete, if at all possible, as they affect the neurologic examination. Simple, rapidly attainable clinical variables that are predictive of poor outcomes include extremes of age, presence of hypotension, hypoxia and/or coagulopathy, increased ICP, decreased GCS score (especially the motor score), and pupillary changes.[8]

TABLE 77-1

Glasgow Coma Scale

Response	Score
Eyes	
• Open spontaneously	4

• Extension (decerebrate rigidity)	2
• No response	1
Best verbal response (Arouse patient with painful stimulus if necessary)	
Oriented and converses	5
Disoriented and converses	4
Inappropriate words	3
Incomprehensible sounds	2

No response	1
Total	3-15

TREATMENT

Desired Outcomes

The overall goal in TBI management is reduction in morbidity and mortality, and optimization of long-term functional outcome for patients. This requires careful attention to the following short-term therapeutic goals: (a) establishment of an adequate airway and maintenance of ventilation and circulation during the initial period of resuscitation and evaluation, (b) maintenance of balance between CDO_2 and $CMRO_2$, (c) prevention or attenuation of secondary neuronal injury, and (d) prevention and/or treatment of associated medical complications.

General Approach to Treatment

② The Brain Trauma Foundation (BTF) has developed an extensive document entitled *Guidelines for the Management of Severe Brain Injury* as a joint initiative with the Guidelines Committee of the American Association of Neurological Surgeons (AANS), the Joint Section on Neurotrauma and Critical Care of the AANS, and the Congress of Neurological Surgeons.[9] This document presently constitute the most widely accepted evidence-based standards, guidelines, and options for the care of patients with severe TBI in the United States.[10] Recommendations are reported as Level I (high quality of evidence), Level II (moderate quality of evidence), or Level III (low quality of evidence). Data show that compliance with the BTF/AANS guidelines results in improved patient outcomes relative to mortality, functional outcome scores, length of hospitalization, and cost. Additionally, guidelines addressing prehospital TBI management[11] and surgical management[12] have also been published, as have TBI management guidelines for infants, children, and adolescents.[13] The recommendations emanating from the published BTF/AANS guidelines on TBI management and various published systematic reviews will be highlighted throughout the remaining portion of this chapter. Recommendations from the BTF/AANS guidelines should serve as the foundation on which all clinical decisions in managing severe TBI are based. Nonetheless, it should be noted that the majority of the guidelines are based on Class II evidence (primarily prospective clinical trials) and Class III evidence (primarily retrospective clinical trials) as few Class I evidence studies (ie, prospective, randomized, controlled trials) are available for treatment of TBI. The pharmacologic management of TBI is summarized in Table 77-2. Recommendations provided in this chapter pertain to adults and children unless specifically noted to the contrary.

TABLE 77-2

Pharmacologic Management of TBI

Hyperosmolar therapy

Mannitol effectiveness in lowering ICP is uncertain (no recommendation level due to insufficient evidence).

Hypertonic saline effectiveness in lowering ICP is uncertain (no recommendation level due to insufficient evidence).

Deep venous thrombosis prophylaxis

LMWH or low-dose unfractionated heparin may be used in combination with mechanical prophylaxis. However, there is an increased risk of expansion of intracranial hemorrhage (Recommendation level III).

Anesthetics, analgesics, and sedatives

Prophylactic administration of barbiturates to reduce burst suppression ECG is not recommended (Recommendation level II B).

High-dose barbiturate administration is recommended to control elevated ICP refractory to maximum standard medical and surgical treatment in adults. Hemodynamic stability is essential before and after barbiturate therapy (Recommendation level II B).

Propofol is recommended for the control of ICP, but not for improvement in mortality or 6-month outcomes. High-dose propofol can produce significant morbidity (Recommendation level II B).

Antiseizure prophylaxis

Prophylactic use of phenytoin or valproate is not recommended for preventing late PTS (occurring later than 7 days) (Recommendation level II A).

Phenytoin is recommended to decrease the incidence of early PTS (within 7 days of injury) (Recommendation level II A).

Levetiracetam cannot be recommended over phenytoin regarding efficacy in preventing early PTS and toxicity. (No recommendation based on insufficient evidence.)

Corticosteroids

The use of steroids is not recommended for improving outcome or reducing ICP in patients with TBI. In patients with moderate or severe TBI, high-dose methylprednisolone is associated with increased mortality and is contraindicated (Recommendation level I).

ECG, electrocardiogram; LMWH, low-molecular-weight heparin; PTS, posttraumatic seizures; TBI, traumatic brain injury. Level I: Recommendation based on a high-quality body of evidence. Level II A: Recommendation based on a moderate-level quality of evidence. Level II B: Recommendation based on a low-quality body of evidence (direct evidence but overall low quality). Level III: Recommendation based on a low-quality body of evidence.

Data from Reference [9].

Pharmacologic Therapy

Initial Resuscitation

③ ④ The first priority in the unconscious patient is airway establishment that facilitates adequate oxygenation and prevents aspiration.[14] Thereafter, restoration and maintenance of systolic blood pressure (SBP) between 120 and 140 mm Hg is desired since having an admission SBP outside this range is associated with increased mortality.[15] More specifically correcting and preventing early hypotension (goal SBP ≥100 mm Hg for patients ages 50 to 69 years or ≥110 mm Hg for patients ages 15 to 49 or over 70 years) is critical as it is among the most powerful predictors of outcome.[9] Isotonic saline (0.9% normal saline) and lactated Ringer's solution have been traditionally used as initial resuscitation fluids of choice in patients with TBI. While some clinicians believe that hypertonic saline (eg, 3% or 7.5% saline) is beneficial in this situation, clinical studies yield equivocal results relative to their superiority over isotonic solutions.[16] Regardless, no clear consensus exists as to the optimal initial resuscitation fluid. Furthermore, the volume of crystalloids administered requires careful monitoring considering there are data associating lower volumes with improved survival.[17] While colloids may be considered an alternative to crystolloid therapy, strong recommendation against their use was made within a consensus statement regarding fluid therapy in neurointensive care patients.[18]

Vasopressors and inotropic agents may be needed to maintain an adequate mean arterial pressure (MAP) if hypotension persists after adequate restoration of intravascular volume. Nonpharmacologic management of intracranial hypertension includes raising the head of the bed 30°, and ventricular drainage if an extraventricular drain (EVD) is present. Figure 77-2 is an algorithm summarizing treatment priorities in the initial management of acute TBI.

FIGURE 77-2

Algorithm for the acute management of the patient with a TBI. (BP, blood pressure; CBC, complete blood count; CPP, cerebral perfusion pressure; CT, computed tomography; EtOH Cp, ethanol plasma concentration; Hct, hematocrit; ICU, intensive care unit; NS, normal saline; OR, operating room; $PaCO_2$, partial pressure of arterial blood carbon dioxide; PRBC, packed red blood cells) *(Reprinted, with permission, from Management of Acute Traumatic Brain. Postresuscitative Care

Following successful resuscitation, priorities shift toward diagnostic evaluation of intracranial and extracranial injuries, and emergent surgical intervention as needed. In many patients, evacuation of intracranial hematomas (ie, epidural, subdural, and intracerebral hematomas) is essential to control ICP and improve outcome. Elevation of depressed skull fractures and debridement of penetrating wound tracts are other important emergent surgical procedures. Decompressive craniectomies (ie, removal of a variable amount of skull bone) with or without temporal or frontal lobectomy may be considered in patients with increases in ICP refractory to more conservative measures.[5] In the largest randomized study to date, patients with TBI and refractory elevated ICPs undergoing decompressive craniectomy had significantly improved survival but higher rates of vegetative state and disability compared with medical therapy.[19] Thus, decompressive surgery's role in adult patients with TBI and refractory ICP remains controversial in light of these quality of life data outcomes.

Continuous ICP monitoring (eg, EVD and/or intraparenchymal fiberoptic catheter) has been the mainstay of ICP monitoring and treatment for decades in patients with severe TBI. Extraventricular drains have a therapeutic advantage over the alternatives but are associated with higher complication rates and can be difficult to place in the setting of the swollen brain. Specifically, while CSF can be drained using this device as a means to lower ICP, the most recent BTF/AANS guidelines have softened the indications for ICP monitoring based on data suggesting that invasive monitoring may lack superiority over clinical/radiologic monitoring; challenging the traditional paradigm.[9,20] If continuous ICP monitoring is employed, the goal should be to treat any ICP values above 22 mm Hg (2.9 kPa) since values above this level are associated with increased mortality.[9]

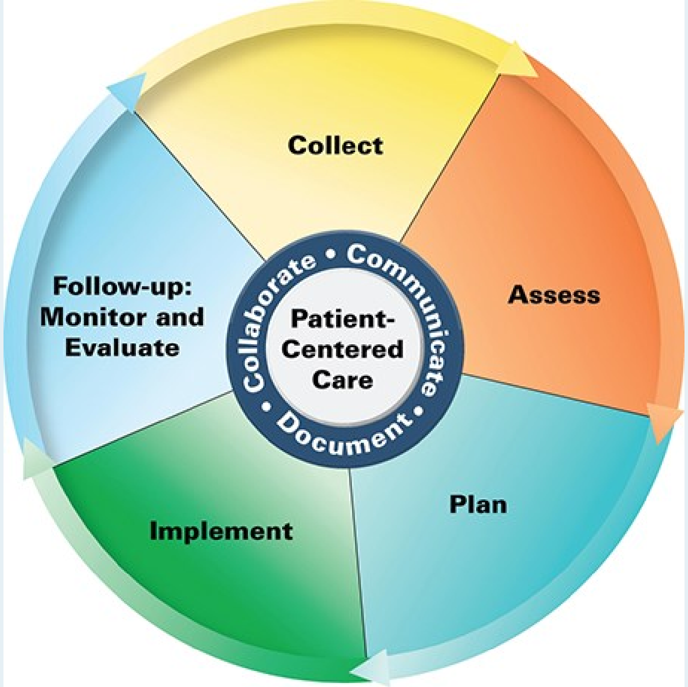
Yet another approach to ICP monitoring or no ICP monitoring is multimodality neuromonitoring (MMM).[21] This practice involves using advanced technologies such as cerebral microdialysis, CBF, brain tissue oxygenation, electroencephalography (EEG), near-infrared spectroscopy, pressure reactivity, and/or transcranial doppler (TCD) monitoring in combination. Although this practice assesses a wide array of cerebral metabolic, oxygen, and cerebrovascular measurements, MMM use is limited to institutions that are equipped to perform such measurements and have individuals capable of utilizing these data to guide expeditious therapy.[22] Furthermore, each of the MMM techniques either alone or in combination with conventional ICP monitoring has limitations and/or potential risks. As such, BTF/AANS guidelines only recommend considering jugular venous oxygen saturation monitoring as a potential advanced monitoring modality to improve outcome in patients with TBI.[9] Biochemical markers (eg, S-100 calcium-binding protein B, neuron-specific enolase, glial fibrillary acid protein, serum substance P[23]) may also have utility in diagnosing and monitoring patients with TBI. However, their role has yet to be defined as each have assorted limitations.[24]

⑤ Another important monitoring parameter within the intensive care environment is the cerebral perfusion pressure (CPP), which is the difference between MAP and ICP (ie, CPP = MAP − ICP). Maintenance of an acceptable CPP is postulated to be critical in reducing cerebral ischemia and secondary injury. The BTF/AANS guidelines recommend maintaining a CPP range between 60 and 70 mm Hg (8.0 and 9.3 kPa).[9] It is also recommended that aggressive attempts to maintain CPP greater than 70 mm Hg (9.3 kPa) in adults should be avoided due to the risk of the acute respiratory distress syndrome. In children, the recommended CPP goal is between 40 and 50 mm Hg (5.3 and 6.7 kPa). While using a fixed target range is the most common approach for monitoring CPP, the concept of individualizing the CPP target range to restore cerebral vasoreactivity has been advocated.[23,25]

In order to achieve the goal CPP, the MAP may need to be increased either through the use of fluids and/or vasopressors, and/or by lowering elevated ICP. In general the goal of volume expansion should be euvolemia to avoid a hypoosmolar state and negative fluid balance.[26] If the hemoglobin is below 7 g/dL (70 g/L; 4.34 mmol/L), transfusion of packed red blood cells (PRBCs) is indicated. Liberal transfusions should be avoided since using a target goal of 10 g/dL (100 g/L; 6.21 mmol/L) is associated with a higher incidence of thromboembolic events without neurologic outcome improvement based on a randomized trial.[27] More data are needed before these findings can be applied to all patients with TBI. Furthermore, erythropoietin use was not associated with an improved neurologic outcome in the same trial.[27] Volume status should be targeted to a central venous pressure of 7 to 12 cm H_2O (0.7-1.2 kPa) if invasive monitoring is employed. After euvolemia is achieved, the patient's head should also be elevated by 30° to promote venous drainage and decrease ICP.[9] If intravascular volume restoration is inadequate in elevating MAP to an acceptable level, hypertension should be induced using vasopressors (eg, norepinephrine, phenylephrine, dopamine)[9] and patients should be monitored for renal dysfunction, lactic acidosis, and signs of peripheral ischemia when they are used, especially in large doses.

PATIENT CARE PROCESS

Patient Care Process for Acute Management of the Brain Injury Patient



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- GCS (Table 77-1), vital signs, physical exam and head computed tomography (CT) scan findings, ABGs, ICP and CPP (if available), laboratory data (see “Clinical Presentation” section)
- Prior and current medications, including alcohol and illicit substances

Assess

- Consistency between with the GCS/physical exam and injuries on head CT scan (ie, could there be other reasons for the neurologic deficit such as intoxication)
- ICP (goal less than 22 mm Hg [2.9 kPa]) and CPP (goal 60-70 mm Hg [8.0-9.3 kPa]) (Fig. 77-2)
- Need for general ICU supportive care including: mechanical ventilation/appropriate oxygenation, stress ulcer prophylaxis, and sedation/analgesia
- For VTE prophylaxis, it is important to determine if pharmacologic prophylaxis is contraindicated due to intracranial bleeding.
- Need for other supportive care measures more specific to TBI including: spine immobilization, seizure prophylaxis, avoiding fever and excessive hyperglycemia, appropriate fluid therapy with a goal of euvolemia, and starting early enteral nutrition

Plan*

- Unless contraindicated, initiate appropriate supportive care measures for the issues outlined above in the Assess section (Fig. 77-2)
- Nonpharmacologic management of increased ICP with first line options (eg, raise head of the bed 30°, open extraventricular drain if ICP is greater than 22 mm Hg [2.9 kPa, if present]) (Fig. 77-2)
- Pharmacologic management of increased ICP with first-line agents (eg, short-acting sedation and analgesia, and hyperosmolar agents [hypertonic saline, mannitol]) (Fig. 77-3 and Table 77-2)

- Avoid low CPP with IV fluid therapy, possible administration of blood products, or vasopressors (eg, norepinephrine, phenylephrine, dopamine) if SBP is less than 100 mm Hg
- Treat hyperthermia, if present, using antipyretic agents and/or cooling blankets
- If ICP is uncontrolled after optimizing first line options for ICP control, move to second line options (eg, pentobarbital, neuromuscular blocking agents, hyperventilation) (Table 77-3)

Implement*

- Work with the medical team on mutually agreeable and patient-centered implementation of treatments where some differences in opinion and practice may exist (eg, initial choice of sedatives, antiseizure medications, or hyperosmolar agents)
- Work with the medical team and nursing staff to implement an understanding of treatment goals (ie, ICP and CPP), as well as clear priorities in treatment selection and escalation among the many options for treating elevated ICP

Follow-up: Monitor and Evaluate

- Monitor ICP and CPP, especially response to therapies for elevated ICP to determine which modalities work best in each patient (Fig. 77-3)
- Other routine monitoring includes GCS, fluid/electrolyte status, ABGs, and vital signs (Table 77-4).
- Medication-specific monitoring includes issues such as: hypotension from sedatives/opiates, hypertriglyceridemia or PRIS from propofol, risk of bleeding/worsening intracranial hemorrhage from VTE prophylaxis agents, antiseizure medication adverse events such as rash, acute kidney injury from mannitol, or hypernatremia/hyperchloremia from hypertonic saline (Table 77-3).
- Discontinue seizure prophylaxis after seven days if no seizures occur in the hospital (Table 77-2)

Collaborate with patient, caregivers, and other healthcare professionals.

Anesthetics, Analgesics, and Sedatives

⑥ Analgesics and sedatives have an important primary role in the management of intracranial hypertension (Fig. 77-3 and Table 77-3) that are directly related to the association of pain, agitation, excessive muscle movement, and resisting mechanical ventilation with transient increases in ICP. Paralytics are a secondary option in refractory patients or during stimulatory procedures in patients with elevated ICP.[28] There is no strong evidence that one agent is superior to another in affecting patient outcomes with severe TBI[29] as their effect on ICP, CPP, and MAP are variable.[29] Morphine sulfate is the most commonly used analgesic and sedative in this setting[9,29] and bolus doses of opiates may increase ICP by increasing CBF.[29] While continuous infusions of fentanyl and sufentanil are gaining in popularity, their use also may be associated with mild elevations in ICP.[9,29] Propofol has become the sedative of choice in the treatment of patients with TBI among many clinicians because of its ease of titration, rapidly reversible effects on discontinuation, and possible neuroprotective effects.[9] Although it is used for sedation in infants and children who are mechanically ventilated in the intensive care unit (ICU) setting, the Food and Drug Administration (FDA) requires that the manufacturer labeling contains specific information that it is not approved for sedation of pediatric patients admitted to an ICU. Propofol's biggest safety concerns is the propofol infusion syndrome (PRIS) characterized by hyperkalemia, hepatomegaly, lipemia, metabolic acidosis, myocardial failure, rhabdomyolysis, renal failure, and death in some cases.[30] While initially reported in children, PRIS can also occur in adults; therefore, doses greater than 5 mg/kg/hr and infusions exceeding 48 hours should be used with extreme caution.[30] Triglyceride concentrations also should be monitored in patients receiving prolonged propofol infusions and/or high dosages considering its lipid emulsion formulation and the potential for inducing hypertriglyceridemia under these conditions. Furthermore, evidence of neurotoxicity from animal studies has raised concerns regarding use of this sedative in patients with TBI.[30] Alternative sedatives include short-acting benzodiazepines (eg, midazolam), especially if there is a reasonable suspicion of alcohol withdrawal as the underlying etiology of the agitation,[31] and intermittent low-dose pentobarbital, ketamine,[32] dexmedetomidine,[33,34] or etomidate (particularly useful in rapid-induction anesthesia). The potential for these agents to decrease MAP and CPP must be monitored closely.[29,30,33] Additionally, the cumulative sedative effects of longer-acting medications, especially benzodiazepines, must be taken into account. The use of any sedative or paralytic agent also must be weighed against its potential to obscure the neurologic examination of the patient.

FIGURE 77-3

Algorithm for the management of increased ICP. (Cp, plasma concentration; EEG, electroencephalogram; ICU, intensive care unit; OR, operating room; PaCO2, partial pressure of arterial blood carbon dioxide.) (*Reprinted, with permission, from Management of acute trauma. In: Richardson M, Chant C, Chessman KH, et al., eds. Pharmacotherapy Self-Assessment Program, 7th ed. Neurology and Psychiatry. Patient with ICP >22 mm Hg^a (>2.9 kPa)
1 Administer^b mannitol (0.25 g/kg IV every 2-4 hours) or hypertonic saline
Open ventriculostomy (if present) for ICP >22 mm Hg (>2.9 kPa)
Consider sedation with propofol (alternative: midazolam) ± short-acting opiate
2 Surgery indicated?
Yes
3 Transport to OR
Go to 4 after return to ICU
No
4 Is ICP >22 mm Hg (>2.9 kPa)^a
Yes
5 Administer sedation as in box 1 (especially if agitated)
No
6 Continuous ICP and vital signs monitoring
Monitor neurologic status
If T >37.5°C (99.5°F), administer acetaminophen, use cooling blanket
7 Is ICP >22 mm Hg (>2.9 kPa)^a
Yes
Optimize first-line therapies:
If ICP continues >22 mm Hg (>2.9 kPa) go to 8
If ICP <22 mm Hg (<2.9 kPa) go to 15
No
8 Second line therapies:
Pentobarbital 25 mg/kg IV, then 1 mg/kg/hr, Cp in 24 hours.
Obtain EEG. Consider short-term hyperventilation to Paco2 30-35 mm Hg (4.0-4.7 kPa.) Consider short-acting neuromuscular blocker if sedation is maximized
Consider furosemide if not hypovolemic
15 ICP >22 mm Hg (>2.9 kPa) over last 24 hours^b
Yes
Go to 1
No
16 Remove ICP monitor
Supportive care
9 Is ICP >22 mm Hg^a (>2.9 kPa)
Yes
10 Is pentobarbital Cp >30 mg/L (>133 µmol/L)?
Yes
11 Is ICP >22 mm Hg (>2.9 kPa)?^a
Yes
12 Reevaluate all medical and surgical options
No
13 Wean pentobarbital over 24 hours
Go to 6
No
14 Partial pentobarbital loading dose based on Cp^c
Increase pentobarbital 1 mg/kg/hr (max dose 3 mg/kg/hr)
Go to 9
No
Go to 15

TABLE 77-3

Medication Dosing and Monitoring in Patients with TBI

Medication (Brand Name)	Adverse Medication Reactions	Monitoring Parameters	Dosage	Comments
Levetiracetam (Keppra)	CNS changes	Seizures, SCr	500-1000 mg IV Q12 hr (during first 14 days)	Caution in patients with renal dysfunction If used for active seizures: increase to 1,000 mg every 12 hours after 14 days, then to 1,500 mg every 12 hours after 28 days
Mannitol (Generic)	Hypotension, renal dysfunction, hyperosmolality	ICP, CPP, BP, serum osmolality, Na, UO, SCr	0.25-1 g/kg IV every 2-4 hours	Avoid in patients with renal failure or CHF
Pentobarbital (Nembutal)	Hypotension, GI hypomotility, induction of hepatic medication metabolism	ICP, CPP, BP, EEG, GI function	10 mg/kg IV over 30 minutes, then 5 mg/kg over 3 hours, then 1 mg/kg/hr	Administer via central line. General dose range for infusion is 1-3 mg/kg/hr
Phenytoin (Dilantin)	Hypotension, dysrhythmias, nystagmus, ataxia, mental status changes, exfoliative dermatitis	Seizures, BP, ECG, phenytoin concentrations, skin	15-20 mg/kg IV over 60 minutes, then 5 mg/kg/day divided every 8 hours or every 12 hours	Administer <50 mg/min; use central line if available Round loading doses up to nearest 250 mg, round maintenance doses up to nearest 25 mg Trauma patients often require higher doses (ie, >6 mg/kg/day) to achieve therapeutic concentrations
Propofol (Diprivan)	Hypotension, hyperkalemia, metabolic, acidosis, rhabdomyolysis, renal failure, hepatomegaly, lipemia	ICP, CPP, BP, SCr, K, arterial pH, triglycerides, lactate	General range: 0.5-3 mg/kg/hr titrated to desired effect	Avoid doses greater than 5 mg/kg/hr or prolonged infusions; not approved for use in children

BP, blood pressure; CHF, congestive heart failure;; GI, gastrointestinal; K, potassium; Na, sodium; SCr, serum creatinine; UO, urine output.

7 High-dose barbiturate therapy (ie, barbiturate coma) has been used for decades in the management of increased ICP despite a lack of evidence documenting beneficial effects on patient morbidity and mortality.[34] Nonetheless, BTF/AANS and pediatric guidelines recommend that high-dose barbiturate therapy be considered in hemodynamically stable patients with severe TBI refractory to maximal medical ICP-lowering therapy and decompressive surgery.[9,13] Prophylactic use of barbiturates is not advocated in light of insufficient evidence supporting this practice and the potential for adverse events (eg, hypotension).[9,13,34] The mechanism responsible for the cerebral protective effects of barbiturates is generally attributed to suppression of cerebral metabolism, thereby cerebral metabolic demands and CBV.[34] Prior to inducing a barbiturate coma, the patient with severe TBI must be mechanically ventilated with continuous monitoring of arterial blood pressure, electrocardiogram (ECG), and ICP. Pentobarbital is the most commonly used barbiturate for this indication, although thiopental also has been used. Pentobarbital should be administered as an IV loading infusion totaling 25 mg/kg (ie, 10 mg/kg over 30 minutes and then 5 mg/kg/hr for 3 hours), followed by a maintenance infusion of 1 to 2 mg/kg/hr.[9,34] If the SBP falls during the loading or maintenance infusions, the rate should be slowed temporarily and blood pressure support initiated. The goal of a

barbiturate coma is to maintain ICP and CPP at the previously discussed target thresholds, as well as EEG burst suppression.[9,34] Although there is a poor correlation between serum pentobarbital serum concentrations and outcomes, the goal is to achieve steady-state concentrations between 30 and 40 mg/L (133 and 178 μmol/L).[34] Initiation of barbiturate therapy withdrawal can occur when ICP has been controlled satisfactorily for 24 to 48 hours and should be tapered over 24 to 72 hours to prevent ICP spikes.

Adverse events associated with high-dose barbiturate therapy involve primarily the cardiovascular system. Hypotension caused by peripheral vasodilation may occur in one of every four patients, necessitating decreasing the barbiturate dose or the administration of fluids and vasopressors to maintain blood pressure.[34] Gastrointestinal (GI) effects of barbiturates include decreased GI muscular tone and decreased amplitude of contraction; however, on emergence from coma, there may be a period of GI hypermotility. Care should be taken to avoid extravasation of barbiturate solutions because severe tissue damage may occur. Therefore, barbiturates should be administered by continuous infusion through a central line dedicated for this purpose. The potential for barbiturates to induce the hepatic medication metabolism of concurrent medications should be also considered. Lastly, the potential for prolonged interference with the neurologic examination of patients with TBI must be considered prior to the initiation of high-dose barbiturate therapy.

Corticosteroids

⑦ Although corticosteroids are effective in preventing or reducing cerebral edema in patients with nontraumatic conditions that produce vasogenic edema, studies in patients with TBI have not demonstrated their ability to lower ICP or improve outcomes.[9,13] Specifically, corticosteroid use following TBI has been associated with increased mortality and complications including GI bleeding, glucose intolerance, electrolyte abnormalities, and infection. The largest investigation to date, known as the Corticosteroid Randomization After Significant Head Injury (CRASH) study, indicated a higher risk of death within 2 weeks of enrollment (relative risk 1.18) in those receiving corticosteroids compared with those receiving placebo.[35] Based on this and several other major randomized trials, the BTF/AANS adult and pediatric guidelines recommend not to use high-dose corticosteroids in patients with moderate-to-severe TBI.[9,13]

Hyperventilation

⑦ The practice of prolonged aggressive hyperventilation ($PaCO_2$ less than 25 mm Hg [3.3 kPa]) to decrease ICP is no longer recommended[8] as this practice is not associated with improved outcomes. As such, BTF/AANS has removed this intervention as a temporizing measure in managing patients with TBI with elevated ICP from their guidelines.[9]

Hypothermia

Therapeutic hypothermia has been an attractive strategy for attempting to minimize secondary brain injury after TBI for decades. The mechanism underlying its protective effect is likely multifactorial, although a reduction in $CMRO_2$ is most frequently cited as the basis of any therapeutic benefits. Although early studies suggested its benefit for patients with TBI, as well as other patient populations with brain ischemia (eg, cardiac arrest patients), large clinical trials data of prophylactic hypothermia have not improved outcomes, and infact indicate poorer outcomes.[9,36–39] Its potential adverse effects include coagulation disturbances, infectious complications, and cardiac arrhythmias. Thus, prophylactic therapeutic hypothermia is not recommended as a routine neuroprotective strategy,[9] except for perhaps patients with TBI with refractory ICP elevations. However, its use in this case is also unclear at best.[40]

Osmotic Agents

⑦ Although a number of osmotic diuretics (eg, urea, glycerol) can be used to decrease ICP, mannitol is the most widely employed.[9,41] Despite the common practice of administering mannitol to patients with suspected or actual increases in ICP following brain injury, clinical trials comparing its effects against placebo have not been performed.[42] Based on this lack of evidence, the BTF/AANS guidelines removed the previous recommendation regarding mannitol's effectiveness for control of increased ICP.[9]

Mannitol's beneficial effects likely relate to (a) an immediate plasma-expanding effect that reduces blood viscosity and increases CBF, and (b) establishment of an osmotic concentration gradient across an intact blood–brain barrier that decreases ICP as water diffuses from the brain into the intravascular compartment.[9] Recommended doses typically range from 0.25 to 1 g/kg IV every 2 to 4 hours with higher doses being used in emergency situations and the lower dose for a maintenance regimen.[43] Increased ICP is reduced within minutes following mannitol administration with a maximum effect within 20 to 60 minutes.[43] To maximize benefit and minimize adverse events, it has been suggested that mannitol be administered as a bolus and not as a continuous infusion in this setting.

Several adverse effects are associated with mannitol.[43] In addition to hypotension resulting from its diuretic effect, a reversible acute renal dysfunction may occur in patients with previously normal renal function after long-term, large-dose administration. Patients particularly susceptible are those with advanced age and preexisting renal dysfunction which is based on data in patients with intracranial hemorrhage.[44] As such, mannitol should be avoided in patients with acute kidney injury or chronic kidney diseases. Acute exacerbation of underlying congestive heart failure and pulmonary edema also may occur following rapid intravascular volume expansion and furosemide is recommended as an alternative diuretic for lowering ICP in these latter patient groups.

While hypertonic saline solutions have been advocated by some as a resuscitative fluid following TBI, solutions ranging from concentrations of 3% to 20% have also been used to acutely lower increased ICP.[43] Doses range from approximately 150 mL of 3% saline solution to 75 mL of 7.5% saline solution to 30 mL of 23.4% saline solution boluses.[43] Saline concentrations greater than 3% should be administered via a central venous catheter.[43] Not only do hypertonic saline solutions create an osmotic gradient in favor of reducing cerebral edema, but they may also have beneficial vasoregulatory, immunologic, and neurochemical effects as well.[45] Plasma expansion may also lead to an increase in CBF. However, the 2016 BTF guidelines do not recommend hypertonic saline due to a lack of supporting evidence[9] consistent with a systematic review which found no mortality benefit or beneficial effect on ICP compared with other ICP-lowering agents.[45] In most of these studies, the goal of therapy was to treat an elevated ICP; however, for some the goal was to increase the serum sodium regardless of ICP. If used in this way, hypertonic saline should target serum sodium concentration less than 160 mEq/L (mmol/L) since additional benefit is unlikely at higher concentrations.[43]

Investigational Therapy

⑧ The steady decrease in morbidity and mortality following severe neurotrauma over the past several decades can be attributed largely to the use of conventional treatment strategies to expeditiously and aggressively manage events resulting in secondary injury (ie, ischemia, hypoxia, increased ICP). Numerous neuroprotective agents targeting specific pathophysiologic processes that are theorized to occur following severe TBI have been investigated over the past three decades in an attempt to further enhance the prospects for a meaningful recovery. Prominent among these strategies have been attempts to modulate calcium influx through the administration of calcium antagonists,[46] glutamate antagonists including magnesium, and the use of antioxidants/free radical scavengers.[47,48] Inhibitors of inflammatory mediators have also been considered as potential neuroprotective agents.[48] Unfortunately, none of these agents to date has demonstrated a significant reduction in morbidity or mortality following severe TBI in clinical trials. There was immense enthusiasm for progesterone as a neuroprotective agent based on two moderately sized clinical studies that demonstrated improved outcome following acute TBI.[49] However, two subsequent large randomized, placebo controlled, prospective trials of progesterone in patients with acute TBI were halted early due to lack of functional outcomes improvement.[50,51] In contrast, interest continues to exist for the pleiotropic cytokine, erythropoietin, as a neuroprotective agent independent of its ability to increase hemoglobin concentrations[47] despite data indicating equivocal results relative to improvement in neurologic outcomes and survival benefits.[52] Other agents that may have beneficial effects in TBI based on limited clinical or epidemiologic data include 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors and sympatholytics such as β-blockers.[53] While two meta-analysis of β-blockers use in patients with TBI demonstrated mortality benefits,[54,55] their usage was associated with increased infection rates, ICU length of stay, and overall hospitalization days.[55] Thus, evaluation of the benefit to risk ratio for this medication class will require additional prospective, randomized, clinical trials in patients with TBI. Miscellaneous agents and therapies being considered as viable neuroprotective agents based on clinical and/or experimental TBI studies include growth hormone, cyclosporine, nitric oxide synthase inhibitor, minocycline, hyperbaric oxygen, and CNS bone marrow stromal cell transplantation.[53] Others have proposed that stimulation of axonal repair processes versus limiting injury may be the most fruitful neuroprotective pathway for future investigations.[47]

The concept of administering commercially available CNS-active agents for nonapproved indications in patients with TBI should presently be considered investigational. Examples include the use of CNS stimulants in the management and rehabilitation of patients with TBI as data supporting this approach are equivocal.[47] Another example is the use of Parkinson's disease medications (eg, amantadine, bromocriptine, carbidopa/levodopa) in patients with severe TBI in an attempt to enhance dopamine release and inhibit reuptake within the injured region of the brain.[56] While intuitively appealing, use of psychoactive agents to improve CNS sequalae should be administered cautiously since large, well-controlled studies with a wide array of agents are lacking. Additionally, the timing for administration of these medications is controversial and the potential for cardiovascular adverse effects in the face of uncertain benefit would suggest that these medications should be reserved for the postacute phase of treatment (ie, weeks to months postinjury).

Acknowledging the complexities surrounding acute TBI, a broad-based, multidisciplinary approach is undoubtedly needed before breakthrough therapies are identified for this multifaceted, catastrophic condition. Examples of these types of initiatives include the International Mission on Prognosis and Clinical Trial Design (IMPACT) study group,[58] and the BRAIN Initiative—Brain Research Through Advancing Neurotechnologies, which is a Presidential and National Institutes of Health focused program aimed at revolutionizing understanding of the human brain launched in 2014.[59]

Treatment and Prophylaxis of Complications

In addition to specific management of TBI problems such as intracranial hypertension, the potential for secondary complications must also considered as a wide variety of complications occur in more than 20% of patients with TBI and are associated with increased mortality and length of stay.[60] Development and implementation of clinical pathways for consistency of care, and clinical investigation of neuroprotective agents are important in advancing TBI treatment in the future.

Posttraumatic Seizures

⑨ It is generally agreed that adult patients who experience one or more seizures following a moderate-to-severe TBI should receive antiseizure medication therapy to avoid increases in $CMRO_2$ that occur with the onset of subsequent seizures and to prevent the development of (sometimes subclinical) status epilepticus associated with increased mortality.[9] Initial therapy should consist of incremental IV doses of diazepam (5-40 mg adults, 0.1-0.5 mg/kg infants and children) or lorazepam (2-8 mg adults, 0.03-0.1 mg/kg infants and children) to terminate any active seizure activity, followed by IV phenytoin to prevent seizure recurrence. Phenytoin dosing regimens for adults and pediatric patients include an IV loading dose of 15 to 20 mg/kg and 10 to 15 mg/kg, respectively, followed by a maintenance dose of 5 mg/kg/day divided into two or three daily doses. Alternatively, fosphenytoin, a water-soluble phosphate ester of phenytoin, can be administered IV or intramuscularly using the same doses, specified as phenytoin equivalents (PE). The merits of preventive antiseizure medication therapy in patients who have not had a seizure postinjury historically is controversial. Risk factors for early posttraumatic seizures (less than 7 days after injury) include a GCS score of less than 10, a cortical contusion, a depressed skull fracture, a subdural hematoma, an epidural hematoma, an intracerebral hematoma, a penetrating head wound, or a seizure within the first 24 hours of injury.[9] In a landmark randomized, placebo-controlled study, the incidence of early posttraumatic seizures in patients receiving placebo was 14.2% compared with 3.6% in patients receiving phenytoin without a significant increase in medication-related adverse events.[61] Thus, phenytoin should be used to prevent seizures in adult and pediatric patients with TBI for the first 7 days after injury[9,13] despite newer data suggesting that phenytoin may not decrease early posttraumatic seizures and may diminish functional outcome after blunt TBI,[62] which is fueling debate challenging this longstanding practice.[63] Valproate therapy is not recommended for patients with TBI, based on a trend for higher mortality compared to short-term phenytoin therapy.[61] Levetiracetam is a potentially attractive option; however, it should be used cautiously as large randomized clinical trials of its use has not been conducted in patients with TBI. Nevertheless, two meta-analyses found no difference in the rate of early posttraumatic seizures between levetiracetam and phenytoin,[64,65] and levetiracetam may have a superior safety profile based on one of these evaluations.[65] In a survey of nearly 70 neurotrauma centers in Europe, levetiracetam has become the antiseizure medication of choice over phenytoin in patients with TBI.[66] If used in TBI patients, the potential for increased levetiracetam systemic clearance should be considered when dosing this agent.[67] The benefits of prophylactic antiseizure medications beyond 7 days have not been demonstrated, and thus their use for this indication is not recommended.[9,13] Unfortunately, despite reducing the incidence of early seizures following brain injury, no beneficial effects have been documented for antiseizure medications on patient mortality or long-term disability.[9]

Supportive Care

While normalizing ICP and maintaining an adequate CPP are the highest priorities in preventing secondary injury following severe TBI, attention also must be given to preventing and/or treating systemic and extracranial complications. One such complication is systemic hypertension, which can be treated using antihypertensives including IV labetalol, nicardipine, and enaliprilat.

Fluid and electrolyte management is another important area of focus in the critically ill patient with a TBI, as common electrolyte disturbances, that should be monitored and treated aggressively, it includes hyponatremia, hypomagnesemia, hypokalemia, and hypophosphatemia.

Furthermore, aggressive nutritional support should be initiated, as early feeding of patients with TBI (ie, by 7 days) may be associated with a trend toward better outcomes in terms of survival and disability.[9,68] Early enteral nutrition, in particular, is associated with better survival and outcome compared with matched controls not receiving early enteral nutrition.[69]

Hyperglycemia (glucose greater than or equal to 160 mg/dL [8.9 mmol/L]) is also common in patients with TBI and is associated with worse outcomes.[70] Thus, intensive insulin therapy versus conventional glucose control should not be used since it is associated with adverse effects on brain glucose metabolism with little to no gain in neurological outcome.[70]

Infectious complications commonly encountered in patients with severe TBI include nosocomial pneumonia, sepsis, urinary tract infections, and meningitis. Treatment of these potentially devastating infections should be aggressive, with careful attention being paid to antibiotic blood–brain barrier penetration for intracranial infections.

Hyperthermia should also be avoided in patients with TBI because patients with elevated temperatures have poorer outcomes than normothermic patients.[71] Hence, aggressive maintenance of a core temperature of less than 37.5°C (99.5°F) using acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and cooling blankets is indicated for patients following severe TBI.

Other important therapeutic interventions include acute gastritis prophylaxis, and prevention of decubiti and contractures. Prevention of thromboembolic events is extremely important in the supportive care in TBI patients since they are high risk of developing this complication.[72] This can be accomplished with the use of intermittent pneumatic compression devices (preferred) or graduated compression stockings initially. Thereafter, the decision to start systemic therapy (eg, low-molecular-weight heparin or unfractionated heparin) depends on multiple factors. A noteworthy study revealed better survival and lower thromboembolic complications in patients with TBI receiving LMWH compared with those receiving unfractionated heparin.[73] Generally, patients who had relatively minor bleeding or no bleeding on the initial CT scan and good ICP control can have pharmacological prophylaxis started within 24 to 48 hours postinjury.[74,75] Patients at moderate-to-high risk of intracranial hemorrhage postinjury can safely receive pharmacologic prophylaxis within the first 72 hours postinjury without a corresponding increase in intracranial hemorrhage compared with patients receiving prophylaxis greater than 72 hours after their TBI.[75] Regardless of initiation time, prophylaxis is continued until patients are ambulatory. Systemic anticoagulation must be used with caution in patients with more severe intracerebral hemorrhage, or in patients who may need to undergo craniotomy early in their course.[9] Monitoring for a coagulopathy is important as the incidence is greater than 30%, and coagulopathy is associated with a significantly longer ICU length of stay and an almost 10-fold increase in mortality.[75] A low platelet count was the strongest predictor of intracranial bleeding progression compared with other coagulation tests in patients with TBI based on a retrospective study.[76] Reversal of coagulopathy with recombinant factor VIIa in critically ill trauma patients with TBI was popular among some practitioners despite lacking an approved indication or large clinical trials demonstrating its safety and efficacy in patients with TBI.[77] However, tranexamic acid is a less expensive hemostatic alternative to recombinant factor VIIa. A randomized, placebo-control trial involving over 12,000 TBI patients known as CRASH-3 revealed that patients with a GCS greater than 3, who received tranexamic acid within 3 hours of injury had a significant decrease in overall mortality by 1.5% compared to patients receiving placebo. The reduced mortality occurred without a difference in adverse events (ie, vascular occlusive events or seizures).[78] However, the mortality benefit was not significant in patients with severe TBI suggesting that it may be more effective in mild-to-moderate TBI as outlined in a meta-analysis.[78,79] Based on these findings, it is unclear if tranexamic acid administration will become the standard of care in non-severe TBI patients.

One of the most common general pharmacokinetic challenges seen in patients with TBI is a larger volume of distribution and more rapid hepatic clearance of medications compared to most other patient populations. These pharmacokinetic changes often make phenytoin optimization and, less commonly, pentobarbital optimization difficult. As such, phenytoin and pentobarbital recommended dosing are weight based, and in the case of phenytoin, usually higher than the 300 mg/day dose commonly seen in ambulatory patients. Augmented renal clearance has also been documented in critically ill patients including patients with TBI affecting medications that are renally eliminated.[80] Furthermore, there can be wide interpatient pharmacodynamic variability in the efficacy of pharmacologic and nonpharmacologic interventions for ICP control. For some patients, there is a high degree of trial and error to find the best combination of interventions that are effective and not contraindicated based on other factors.

CLINICAL PATHWAYS/GUIDELINE IMPLEMENTATION

Use of clinical pathways and formal TBI management guidelines/standardized protocols have been demonstrated to improve TBI patient mortality in studies focused on intracranial hypertension.[81,82] Aggressive ICP monitoring has been associated with improved outcomes in patients with moderate-to-severe TBI as well.[83] Furthermore, a cost–benefit analysis revealed that adoption of the BTF/ASSN guidelines resulted in more than 3,600 lives saved among adult patients with severe TBI admitted annually to US hospitals as the proportion of patients having a good outcome based on their Glasgow Outcome Scale (GOS) was estimated to increase from 35% to 66%. This resulted in an overall estimated annual total cost savings exceeding $4 billion.[84] Unfortunately, improved outcomes are universally reported as there is a wide guideline compliance variability despite the BTF/AANS guidelines availability for over two decades.[10,85] Regardless, few practitioners would dispute the overall importance of integrating current evidence-based management guidelines into clinical practice as a means to optimize care and improve the functional outcome of patients.[48,86]

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes is summarized in Table 77-4. Patients with severe TBI initially require ICU monitoring with the goals of maintaining or reestablishing neurologic and systemic homeostasis, as well as readily detecting any neurologic deterioration. This requires frequent evaluation of the patient’s neurologic status (eg, GCS), measurement of vital signs, urine output, and arterial oxygen saturation, and ICP in patients with an ICP monitor in place. Careful attention must be paid to the potential development of various electrolyte, mineral, and acid–base disturbances; coagulopathies; and infections by obtaining appropriate laboratory tests on a daily basis initially. The intensity of monitoring will be a function of the relative degree of patient’s neurologic and hemodynamic stability in the hours and days following the neurologic insult. Lastly, radiologic tests (eg, CT scans) are essential not only for the initial diagnostic evaluation, but also as means to evaluate the etiology for any subsequent neurologic deterioration.

TABLE 77-4

Evaluation of Therapeutic Outcomes

General	GCS: Record hourly initially, decrease frequency as neurologic status stabilizes Vital signs (BP, HR, RR, temperature): Record hourly initially, decrease frequency as neurologic status stabilizes UO: Record hourly initially, decrease frequency as neurologic status stabilizes Arterial oxygen saturation: Continuously while in ICU
Risk of increased ICP	ICP: Record hourly, decrease frequency as ICP stabilizes <22 mm Hg (2.9 kPa) (usually not until 48-72 hours postinjury at a minimum) CPP: Record hourly, decrease frequency as CPP stabilizes in the desired range[a]
Laboratory tests	Ethanol concentration and urine toxicology results : On admission ABGs: Daily at a minimum while intubated, repeated as needed based on pulmonary instability requiring ventilator setting changes CBC: Daily while in ICU Serum electrolytes (Na, K, Cl): Daily while in ICU. Serum sodium and osmolality may be monitored as frequently as every 6 hours if osmotherapy (mannitol, furosemide, hypertonic saline) is being used. Minerals (Mg, Ca, P): Daily initially until concentrations stable
Radiologic procedures	CT scan: Postresuscitation initially with repeat scan(s) as needed based on degree of neurologic instability (eg, decrease in GCS) or initial CT appearance

BP, blood pressure; Ca, calcium; CBC, complete blood count; Cl, chloride; CT, computed tomography; HR, heart rate; K, potassium; Mg, magnesium; Na, sodium; P, phosphorus; RR, respiratory rate; UO, urine output.

[a] Continuous monitoring mandated initially if technologically feasible.

CONCLUSION

Traumatic brain injuries are exceedingly common and often associated with devastating consequences in both morbidity and mortality. Unraveling the complex pathophysiology of secondary injury following severe TBI has failed to yield major advances to attenuate or reverse these consequences to date. Furthermore, review of several traditional treatment modalities has resulted in recommendations against their use. Adherence to best management practices relative to aggressive treatment of increased ICP, supportive care, and prevention of complications offers victim of severe TBI a promise of improved outcomes. Commitment to this condition at the national level may be the turning point to breakthrough therapies of the future.

SELF-ASSESSMENT QUESTIONS

1. Which of the following events is the most common cause of TBI?

   A. Gunshot wounds

   B. Sport and recreational accidents

   C. Motor vehicle accidents

   D. Falls

2. Which of the following is thought to be a key component in the pathophysiology of secondary neuronal injury after TBI?

   A. Hyperglycemia

   B. Cellular calcium influx

   C. Inflammatory mediators

   D. Lactic acidosis

3. Which of the following ranges of GCS scores is consistent with a severe TBI?

   A. 1-3

   B. 3-8

   C. 9-12

   D. 13-15

4. During the initial resuscitation period after a severe TBI, which of the following are the minimum goal systolic blood pressure (SBP), and the ideal SBP range that are associated with improved outcomes?

   A. Minimum >60 mm Hg, ideal range 60 to 70 mm Hg

   B. Minimum >100 mm Hg, ideal range 100 to 120 mm Hg

   C. Minimum >100 mm Hg, ideal range 120 to 140 mm Hg

   D. Minimum >120 mm Hg, ideal range >140 mm Hg

5. Which of the following represents the goal ICP and CPP values in an adult patient with a severe TBI?

   A. ICP <20 mm Hg (2.7 kPa), CPP >50 mm Hg (6.7 kPa)

   B. ICP <20 mm Hg (2.7 kPa), CPP 60-70 mm Hg (8.0-9.3 kPa)

   C. ICP <22 mm Hg (2.9 kPa), CPP 60-70 mm Hg (8.0-9.3 kPa)

   D. ICP <22 mm Hg (2.9 kPa), CPP >70 mm Hg (9.3 kPa)

6. Which of the following is the primary advantage of a ventriculostomy over an intraparenchymal ICP monitor?

    A. Cerebrospinal fluid can be drained to lower ICP.

    B. Less difficult and invasive to perform placement.

    C. Lower complication rate.

    D. Superior outcomes in clinical trials.

7. Which of the following is generally the sedative of choice for controlling ICP in patients with TBI?

    A. Midazolam

    B. Pentobarbital

    C. Propofol

    D. Dexmedetomidine

8. Which of the following is the best initial therapy for lowering ICP in a patient with a severe TBI and pulmonary edema from congestive heart failure?

    A. Mannitol

    B. Hypertonic saline

    C. Pentobarbital coma

    D. Furosemide

9. Which of the following is a primary advantage of hypertonic saline over mannitol as an osmotic agent for lowering ICP?

    A. Stronger diuretic effect

    B. Improved mortality in large trials

    C. Lower risk of hyperglycemia

    D. Lower risk of acute renal dysfunction

10. A patient with a severe TBI is having intermittent ICPs in the mid-to-high 20s (mm Hg; or ~3.3-3.9 kPa) despite treatment with a propofol infusion (4 mg/kg/hr) and intermittent doses of mannitol and hypertonic saline. Which of the following should be added for ICP control now?

    A. Fentanyl infusion

    B. Neuromuscular blocker

    C. Pentobarbital coma

    D. Furosemide

11. The neurosurgical team wants to use a neuromuscular blocker as a second-line agent for ICP control in a patient whose ICPs are still elevated. Which of the following is a critical factor in this decision?

    A. Sedation doses must be maximized before use.

    B. A long-acting neuromuscular blocker is preferred.

C. Sedation should be temporarily held to assess efficacy.

D. Monitoring for hypertriglyceridemia before use.

12. Which of the following is the most common dose-limiting adverse event side of pentobarbital coma?

A. Hypotension

B. GI hypomotility

C. Pulmonary edema

D. Hypertriglyceridemia

13. Which of the following describes when the use of therapeutic hyperventilation should be considered in managing patients with TBI?

A. Routine prophylactic use to prevent ICP elevations in all patients with TBI

B. A standard first-line treatment for ICP elevations in all patients with TBI

C. A second-line therapy with a $PaCO_2$ goal of 25-35 mm Hg (3.3-4.7 kPa)

D. A second-line therapy with a $PaCO_2$ goal of less than 25 mm Hg (3.3 kPa)

14. Which of the following best describes drug selection for seizure prophylaxis after a severe TBI?

A. Levetiracetam is preferred because it doesn't require serum monitoring, a better safety profile, and was superior in large randomized trials (RCTs).

B. Valproic acid can be used as a first-line agent because it is available in an IV form and performed similarly to phenytoin in a large RCT.

C. Phenytoin is the drug of choice and can be used for seizure prophylaxis in the early (within the first 7 days) and late (after 7 days) periods.

D. Phenytoin should be used in the early period in patients without seizures and it still has the highest quality of data supporting its use (ie, RCT).

15. Which of the following best describes appropriate use of LMWH products, low-dose unfractionated heparin (LDUH), and intermittent pneumatic compressions devices (IPC) for venous thromboembolism prophylaxis in patients with severe TBI?

A. Only IPCs should be used during the ICU stay due to the increased risk of further intracranial bleeding with LMWH and LDUH.

B. Reviews suggest that LMWH or LDUH can be started within the first 24 hours after injury in all patients with TBI.

C. LMWH or LDUH should be held for 72 hours post injury in patients with a moderate-to-high risk of further intracranial hemorrhage.

D. LMWH or LDUH can be started within 24 to 48 hours post injury in all patients with severe TBI and good ICP control.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Falls are the leading cause of TBI in the United States. See the "Epidemiology" section for more information.

2. **B.** Cellular calcium influx is a key step in the pathophysiology of secondary neuronal injury. See the "Primary and Secondary Brain Injury Pathophysiology" section for more information.

3. **B.** A GCS score of 3-8 indicates a severe TBI. See the "Clinical Presentation" section and Table 77-1 for more information.

4. **C.** During initial resuscitation after TBI, avoiding SBP <100 mm Hg and maintaining SBP 120-140 mm Hg were both associated with improved outcomes. See the "Initial Resuscitation" section and Fig. 77-2 for more information.

5. **C.** In adult patients with TBI, the goal ICP is <22 mm Hg (2.9 kPa) and goal MAP is 60-70 mm Hg (8.0-9.3 kPa). See the "Postresuscitative Care" section and Fig. 77-2 for more information.

6. **A.** The primary advantage of an extraventricular drain is the ability to lower ICP by draining CSF. See the "Postresuscitative Care" section for more information.

7. **C.** Propofol is generally considered the sedative of choice for ICP control because of rapid titratability. See the "Anesthetics, Analgesics, and Sedatives" section, Fig. 77-3, and Table 77-2 and 77-3 for more information.

8. **D.** Furosemide is not normally a first-line agent, but would be preferred in this case because of cardiogenic pulmonary edema. See the "Osmotic Agents" section for more information.

9. **D.** Mannitol can cause acute renal dysfunction. This is not an adverse effect of hypertonic saline. See the "Osmotic Agents" section for more information.

10. **A.** Fentanyl infusion is the only option listed that is a first-line option for ICP control. See the "Anesthetics, Analgesics, and Sedatives" section and Fig. 77-3 for more information.

11. **A.** Sedation should always be maximized prior to using neuromuscular blockers to avoid awareness of paralysis. See the "Anesthetics, Analgesics, and Sedatives" section and Fig. 77-3 for more information.

12. **A.** Hypotension is a common adverse event of pentobarbital. See the "Anesthetics, Analgesics, and Sedatives" section and Table 77-2 and 77-3 for more information.

13. **C.** Hyperventilation to a goal of 25-35 mm Hg (3.3-4.7 kPa) can be considered as a second-line therapy for treating ICP elevations. See the "Hyperventilation" section and Fig. 77-3 for more information.

14. **D.** Even though levetiracetam use is increasing, the authors still recommend phenytoin as the first-line agent for seizure prophylaxis due to it being the only drug to be effective for this indication in a large RCT. See the "Posttraumatic Seizures" section, Fig. 77-2, and Table 77-2 and 77-3 for more information.

15. **C.** An evidence-based review recommends holding pharmacologic prophylaxis for 72 hours in patients with moderate-to-high risk of intracranial hemorrhage. See the "Supportive Care" section for more information.

Chapter 78: Parkinson Disease

Jessa M. Koch; Khashayar Dashtipour; Jack J. Chen

KEY CONCEPTS

KEY CONCEPTS

1. To optimize long-term therapeutic outcomes, minimize adverse effects, and improve quality of life for individuals with idiopathic Parkinson disease (PD), clinicians need to (1) continually access motor and nonmotor symptoms, (2) thoughtfully consider initial and adjunctive therapies, and (3) continually adjust medication dosages throughout the course of this illness.
2. In general, treatment should be initiated when the disease begins to interfere with activities of daily living, employment, or quality of life.
3. Surgery is an option for patients who require additional symptomatic relief or control of motor complications.
4. Anticholinergic medication can be useful for mild symptoms of PD but, due to adverse medication effects, it should be used with caution in older patients and those with pre-existing cognitive difficulties.
5. Monotherapy with amantadine or the irreversible monoamine oxidase type B (MAO-B) inhibitors provide symptomatic benefit, but less than that of dopamine agonists or carbidopa/levodopa (L-dopa).
6. Carbidopa/L-dopa is the most effective medication for symptomatic treatment.
7. Most patients treated with carbidopa/L-dopa will develop motor complications (eg, fluctuations and dyskinesias).
8. MAO-B inhibitors (irreversible and reversible), catechol-*O*-methyltransferase (COMT) inhibitors, and adenosine A2 receptor antagonists are useful add-on therapies to attenuate motor fluctuations in patients treated with carbidopa/L-dopa.
9. Amantadine is a useful add-on agent to attenuate dyskinesias.
10. Dopamine agonists are effective and, compared to L-dopa, associated with less risk of developing motor complications. They do however carry a greater risk for psychiatric symptoms, such as hallucinations and impulse control disorders.

BEYOND THE BOOK

BEYOND THE BOOK

Refer to Chapter 69: Parkinson Disease: Slow and Shaky Level III in *Pharmacotherapy Casebook: A Patient-Focused Approach* and read the initial patient presentation to answer the following questions.

(1) What medications may be considered for treatment of this patient's uncontrolled PD? List the different medication options along with specific treatment considerations for this particular patient such as adverse effects, tolerability concerns, etc.

(2) This patient shares that they just saw a commercial for a new medication for Parkinson Disease, opicapone, and wants to know if this would be an option right now. Explain why opicapone would not be an initial medication choice for this patient.

(3) Upon closer evaluation of the patient case, you notice that there is no history of past medications this patient has used. You would like to get this information to assess for medication-induced parkinsonism. Create a list of medications that can cause parkinsonian symptoms, and the mechanism by which they can induce symptoms.

INTRODUCTION

The presence of bradykinesia (slowness of movements) along with tremor at rest, rigidity, and postural instability (instability of balance) is considered the hallmark motor features of idiopathic Parkinson disease (PD), a disorder of the extrapyramidal system. These clinical features of PD were adeptly described in 1817 by James Parkinson.[1]

EPIDEMIOLOGY

Up to 1 million individuals in the United States have PD, and this is only projected to increase over time.[2] The overall incidence rate of PD (ie, number of persons newly diagnosed with PD per year) is age- and sex-dependent. For individuals between the ages of 40 and 49 years, there are approximately 3 per 100,000 persons diagnosed with PD. However, for females in the ninth decade of life (ie, 80-89 years), the prevalence is 10 per 100,000 persons compared to males with an incidence of 250 per 100,000 persons.[3] The usual age at time of diagnosis ranges between 55 and 65 years, and overall, PD affects less than 0.5% of people in their 60s and 2.5% of those older than 80 years.[4]

ETIOLOGY

Parkinson disease occurs sporadically, and the true etiology is unknown. However, the etiopathogenesis of PD likely involves environmental and genetic factors.[5] At the cellular level, degeneration of dopaminergic neurons (axons and soma) projecting from the substantia nigra pars compacta (SNc) to the striatum (caudate nucleus and putamen) is a hallmark of PD.[6] Additionally, neurons in autonomic ganglia, enteric nervous system, limbic system, olfactory bulb, spinal cord, and neocortex are affected. The underlying mechanisms are interconnected and multifaceted with the involvement of toxic biochemical reactions (excitotoxicity, nitric oxide toxicity, oxidative stress), abnormal cellular and cell death signaling pathways (apoptosis, inflammation), dysfunctional organelles (lysosomes, mitochondria), and dysfunctional protein degradation systems (autophagy, ubiquitin proteasomal system) resulting in cytoplasmic protein (α-synuclein) accumulation.[7] Several of these mechanisms result in excessive production of free radicals which exert stress on cells by damaging membranes and organelles. The SNc and the striatum are regions characterized by high levels of oxidative stress due to dopamine degradation and the Fenton reaction (Fig. 78-1).[8] Normally, intrinsic antioxidants (eg, glutathione) buffer against oxidative stress, but in PD, this buffer might be impaired or overwhelmed. Pathologic findings reveal a correlation between the extent of nigrostriatal dopamine loss and the severity of certain PD motor features (eg, bradykinesia and rigidity). At the time of PD onset, the estimated loss of SNc neurons and striatal dopamine content are 30% and 50%, respectively.[9] The loss of striatal dopamine exceeds the loss of SNc cell bodies because cellular degeneration begins in the distal presynaptic axon terminals and proceeds over time toward the cell body/soma (ie, "dying back" axonopathy).[9]

FIGURE 78-1

Dopamine metabolism results in hydrogen peroxide (H_2O_2) formation. In the Fenton reaction, H_2O_2 accepts an electron from ferrous iron (Fe^{2+}) to produce ferric iron (Fe^{3+}) and the hydroxyl radical (HO^*). Fe^{3+} is reduced back to Fe^{2+} by another molecule of H_2O_2, forming a hydroperoxyl radical (HOO^*). The radicals damage cell membranes and organelles (eg, mitochondria) and also induce apoptotic signaling. (COMT, catechol-*O*-methyltransferase; DOPAC, 3,4-dihydroxyphenylacetic acid; GSH, glutathione; GSSG, glutathione disulfide; H^+, proton; H_2O, water; HVA, homovanillic acid; L-AAD, L-aromatic amino acid decarboxylase; OH^-, the hydroxide ion; MAO-B, monoamine oxidase B).

Aging, genetic constitution, lifestyle, and environmental factors likely increase an individual's risk for PD.[7,10] Epidemiologic research links environmental factors (eg, chronic exposure to pesticides), with an elevated risk. Cigarette smoking and caffeine consumption are consistently associated with a lower risk.[11,12] Genetic polymorphisms and epigenetics also modify an individual's risk for PD.[5,7,13] It is known that pesticide exposure and genetic forms of PD (eg, leucine-rich repeat kinase 2 [LRRK2], parkin, and PTEN-induced putative kinase 1 [PINK1]) are associated with mitochondrial dysfunction and oxidative stress.[7]

PATHOPHYSIOLOGY

A function of the basal ganglia (composed of subcortical structures including the substantia nigra, striatum, globus pallidus, and subthalamic nucleus [STN]) is to regulate voluntary movement. These subcortical structures exist in duplicate, with one structure on each side of the midline. The substantia nigra consists of two parts: the SNc and pars reticulata (SNr). Neuronal projections from the SNc to the striatum are referred to as the *nigrostriatal pathway*. The striatum conveys signals to the SNr, via the dopamine$_1$ (D_1) direct and the dopamine$_2$ (D_2) indirect pathways (Fig. 76-2A). The SNr (which is closely linked to the globus pallidus interna [GPi]) receives signals from the striatum and conveys final processed signals to the thalamus, which serves as the "gateway" to the motor cortex. When examining the basal ganglia circuitry, it is important to note that striatal D_1 receptors are coupled to adenylate cyclase and mediate postsynaptic depolarization; thus, D_1 receptor activation results in stimulation of the striatal GABAergic neurons.[14,15] Increased activity of the direct pathway results in increased movement. In contrast, striatal D_2 receptors are coupled to a guanosine triphosphate-binding protein and mediate postsynaptic hyperpolarization; thus, D_2 receptor activation results in inhibition of striatal GABAergic neurons, and a net reduction in movement.[14] Additionally, adenosine A2A receptors (A2AR) are located in the striatopallidal GABAergic neurons within this indirect pathway.[15] In PD, reduced dopaminergic activation of D_1 and D_2 receptors and the sequential downstream effect on signaling pathways result in a net inhibitory tone on the thalamus (Fig. 76-2B). Dopaminergic therapies help restore functional activity within the D_1 and D_2 pathways with the latter primarily responsible for mediating clinical improvements. Antagonism of A2ARs (ie, inhibition of the indirect pathway) can result in prolongation of dopaminergic action in PD and is the mechanism of action behind the non-dopaminergic treatment option, istradefylline.[15,16]

FIGURE 78-2

(*A*) Dopaminergic pathways of the basal ganglia–thalamocortical circuit. Activation of D_1 and D_2 receptors results in depolarization and hyperpolarization, respectively, of postsynaptic neurons. (Red dots and lines represent excitatory input; black dots and lines represent inhibitory input.) (*B*) In Parkinson's disease, degeneration of presynaptic nigrostriatal neurons results in inhibition of the thalamocortical circuit and reduced signaling to the motor cortex. (*Dashed lines* represent reduction of neurotransmitter activity; GPe, globus pallidus externa; GPi, globus pallidus interna; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus.)

Within the SNc, histopathologic features of PD are (1) depigmentation of dopamine-producing neurons (ie, loss of SNc neurons) and (2) presence of Lewy bodies (cytoplasmic filamentous aggregates composed of the protein α-synuclein) in the remaining neurons.[6] Lewy bodies appear in association with adjacent gliosis (ie, a response of glial cells to injury), and the formation and spread of Lewy pathology is proposed to occur in stages. In the premotor stage of PD, Lewy bodies are found in the medulla oblongata, locus coeruleus, raphe nuclei, enteric nervous system, and olfactory bulb. This provides anatomic correlates to observations that mood (eg, anxiety, depression) and peripheral symptoms (eg, constipation, impaired olfaction) are present in premotor stages of PD. Lewy pathology develops peripherally in the enteric nervous system and olfactory system and may spread anterogradely or retrogradely to the brain.[17] With the development of Lewy pathology in the midbrain (particularly the SNc), motor features begin to emerge. In advanced stages, Lewy pathology spreads to the cortex, and this may correlate with cognitive and additional behavior changes. Recent investigations have shown that α-synuclein pathology can propagate into adjacent healthy neurons in a nontoxic infectious manner that results in subsequent neuronal toxicity.[3,18]

The synaptic organization of the basal ganglia also involves a variety of other neurotransmitters and neuromodulators, including acetylcholine, adenosine, enkephalins, γ-aminobutyric acid (GABA), glutamate, serotonin, and substance P. The potential role for medication modulation of these other neurotransmitters and receptor types is an active area of research and novel therapeutic discovery.[19]

Atypical parkinsonian disorders such as multiple system atrophy and progressive supranuclear palsy are characterized by damage to postsynaptic striatal neurons and dopamine receptors. Therefore, dopaminergic therapies are less efficacious in atypical parkinsonism.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Idiopathic PD

General Features

- The patient exhibits bradykinesia (slowness of movements) and at least one of the following: resting tremor, rigidity, or postural instability. Asymmetry of motor features is supportive.

Motor Symptoms

- The patient experiences hypokinetic movements, decreased manual dexterity, difficulty arising from a seated position, diminished arm swing during ambulation, dysarthria (slurred speech), dysphagia (difficulty with swallowing), festinating gait (tendency to pass from a walking to a running pace), flexed posture, "freezing" at initiation of movement, hypomimia (reduced facial animation), hypophonia (reduced voice volume), and micrographia (Fig. 78-3).

Autonomic and Sensory Symptoms

- The patient experiences bladder dysfunction, constipation, diaphoresis, fatigue, olfactory impairment, orthostatic intolerance, pain, paresthesia, paroxysmal vascular flushing, seborrhea, sexual dysfunction, and sialorrhea (drooling).

Mental Status Changes

- The patient experiences anxiety, apathy, bradyphrenia (slowness of thought processes), cognitive impairment, depression, and hallucinosis/psychosis.

Sleep Disturbances

- The patient experiences excessive daytime sleepiness, insomnia, obstructive sleep apnea, and rapid eye movement (REM) sleep behavior disorder.

Laboratory Tests

- No laboratory tests are available to diagnose PD.

Other Diagnostic Tests

- Genetic testing is not routinely helpful.
- Neuroimaging may be useful for excluding other diagnoses.
- Medication history should be obtained to rule out medication-induced parkinsonism.

The clinical diagnosis of PD is based on the presence of bradykinesia and at least one of three other features: muscular rigidity, resting tremor, and/or postural instability (Table 78-1).[20] Asymmetry of motor features is a supportive finding. It is important to note that tremor is not always present at the time of diagnosis, and postural instability typically occurs in later stages of PD. Overall, a diagnosis of PD can be made with a high level of confidence in a patient who has bradykinesia (along with rest tremor and/or rigidity), prominent asymmetry, and a good response to dopaminergic therapy. For the diagnosis of PD, other conditions must be reasonably excluded (see Table 78-1). Medication-induced parkinsonism can mimic PD and is the second most common form of parkinsonism.[21] It is important to assess for recent use of medications, especially medications that block D_2 receptors, such as antipsychotics (eg, haloperidol), metoclopramide, or phenothiazine antiemetics (eg, prochlorperazine).[21] Neurologic conditions that can be mistaken for PD include atypical parkinsonisms and tremor disorders (eg, dystonic tremor, essential tremor). Because the management and prognosis of PD differ from these other conditions, obtaining an accurate diagnosis is important. When the diagnosis is in doubt, referral to a movement disorders specialist is recommended. Currently, efforts are underway to develop and validate diagnostic tools based on personalized clinical, laboratory, imaging, and genomics data.

Parkinson disease develops insidiously and progressively worsens over many years. Tremor of an upper extremity occurring at rest (and occasionally an action or postural tremor) is often the sole presenting complaint. However, only two-thirds of patients with PD have tremor on diagnosis, and some never develop this sign. Tremor in PD is present most commonly in the hands, sometimes with a characteristic pill-rolling motion. Less commonly, tremor may involve the jaw or legs. Like other motor features of PD, resting tremor often begins unilaterally and becomes bilateral with disease progression. Stressful or emotional (either negative or positive) situations often increase the tremor amplitude and severity. Usually, tremor is absent during sleep. Although resting tremor is visibly noticeable in PD and may cause social embarrassment for the patient, it often is the least physically disabling of the motor features.

Rigidity is the increased muscular resistance to passive range of motion and most commonly affects the upper and lower extremities and occasionally the neck. If tremor is present in the affected extremity, the rigidity is associated with a cogwheel or ratchet-like quality upon examination. Facial muscles also are affected, resulting in hypomimia that may be erroneously interpreted as apathy, depression, or unfriendliness.

Hypokinesia is a decreased movement and often described as either bradykinesia (slowness of movement) or akinesia (absence of movement). Movement in PD is often slow throughout an intended action and difficulty with the initiation of movement also occurs. A progressive slowing and decline in dexterity may impair tasks such as hand clapping, finger tapping, and handwriting (Fig. 78-3). Intermittent immobility or akinesia (freezing) is another common characteristic. Freezing is especially likely to occur in situations such as when walking through a narrow doorway or initiating a turn.

The clinical diagnosis of PD relies on motor findings; however, neuroimaging along with nonmotor markers (eg, REM sleep behavior disorder, olfactory impairment) may someday aid in the detection of PD in premotor or prodromal stages (ie, before onset of motor impairment).[22]

Postural instability, most common in advanced stages of PD, is one of the most disabling problems of PD because it increases the fall risk and is least amenable to pharmacotherapy.[23] Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait with difficulty halting their steps while in motion (festination) and freezing, which also increases the risk of falling.

Nonmotor symptoms are common in PD and must be identified, assessed, managed, and monitored (Table 78-2). These include anxiety, cognitive impairment, constipation, daytime sleepiness, depression, drooling, dysphagia, falling, fatigue, impulsivity, insomnia, orthostatic hypotension, overactive bladder, pain, hallucinations/psychosis, REM sleep behavior disorder, and restless legs syndrome.[24] As a component of managing these nonmotor symptoms, it is important to maintain continuous surveillance of prescription and nonprescription medications for potential adverse effects that can exacerbate, mimic, or precipitate nonmotor symptoms. If feasible, any identified offending medication should be deprescribed.

FIGURE 78-3

Example of micrographia in a patient with Parkinson disease. As the sentence “Today is a sunny day in California” is repeatedly handwritten, progressive diminution of letter size occurs (micrographia). The height of each lined row is approximately 5/16 in. (8 mm).

TABLE 78-1

Diagnostic Criteria and Differential Diagnosis for Parkinson Disease

Parkinson Disease

- Step 1: Presence of bradykinesia and at least one of the following: resting tremor, rigidity, or postural instability
- Step 2: Exclude other types of parkinsonism or tremor disorders (see "Differential Diagnosis" below)
- Step 3: Presence of at least three supportive positive criteria:
  - Asymmetry of motor signs/symptoms
  - Unilateral onset
  - Progressive disorder
  - Resting tremor
  - Excellent response to carbidopa/L-dopa
  - L-dopa response for 5 years or longer
  - Presence of L-dopa dyskinesias

Differential Diagnosis

- Essential tremor
- Pharmacotoxicity (medication-induced)
  - Antiemetics (eg, metoclopramide, prochlorperazine)
  - Antipsychotics (eg, chlorpromazine, fluphenazine, haloperidol, olanzapine, risperidone, thioridazine)
  - Other medications (α-methyldopa, cinnarizine, flunarizine, tetrabenazine)
- Environmental toxicity (eg, manganese, organophosphates)
- Infections (eg, human immunodeficiency virus, subacute sclerosing panencephalitis)
- Metabolic disorder (eg, hypothyroidism, parathyroid abnormalities)
- Neoplasms, strokes, traumatic lesions involving the nigrostriatal pathways
- Normal-pressure hydrocephalus
- Parkinsonism with other neuronal system degenerations
  - Corticobasal ganglionic degeneration
- Multiple-system atrophies
- Progressive supranuclear palsy
- Familial (hereditary) parkinsonism
  - Autosomal dominant
  - α-Synuclein gene mutation (*PARK1* and *PARK4*)
  - L-responsive dystonia
  - Leucine-rich repeat kinase 2 (LRRK2) mutation
  - Rapid-onset dystonia parkinsonism (DYT12)
  - Spinocerebellar ataxias (SCA2, SCA3)
- Autosomal recessive
  - Wilson disease
  - Young-onset parkinsonism (DJ-1, parkin, PINK1)
- X-linked recessive
  - Fragile X tremor/ataxia syndrome (FXTAS)
  - Lubag (DYT3 or Filipino dystonia parkinsonism)

TABLE 78-2

Nonmotor Symptoms and Possible Treatments

Symptoms	Possible Treatments
Anxiety	Cognitive behavioral therapy, selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, minimize “off” times
Cognitive impairment	Eliminate anticholinergic agents, add cholinesterase inhibitor
Constipation	Fiber, hydration, exercise, laxatives, stool softeners
Daytime sleepiness	Proper nighttime sleep hygiene, reduce dose of dopaminergic medications, eliminate anticholinergic agents if possible, referral to sleep specialist to rule outsleep apnea and sleep disorders
Depression	Selective serotonin reuptake inhibitor, serotonin norepinephrine reuptake inhibitor, cognitive behavioral therapy
Drooling	Local injection of botulinum toxin, atropine sublingual drop, glycopyrrolate, ipratropium sublingual spray
Dysphagia	Referral to speech therapist, dysphagia diet, avoid anticholinergic medications, manage dry mouth
Fatigue	Caffeine, armodafinil, modafinil, proper nighttime sleep hygiene, referral to sleep specialist to rule out sleep disorder
Falling	Assess for orthostatic hypotension, referral to physical therapy, assistance with ambulation, minimize risk for bone fractures, treat osteoporosis
Hallucinations/psychosis	Dose reduction and/or elimination of adjunctive medications, especially anticholinergic agents; consider addition of pimavanserin, quetiapine or clozapine; Note: pimavanserin is FDA-approved for psychosis in PD
Impulse control disorder	Discontinue dopamine agonist or add clozapine, quetiapine, or naltrexone
Insomnia	Cognitive behavioral therapy-insomnia; nonbenzodiazepine $GABA_A$ agonists, trazodone
Orthostatic hypotension	Reduce dose of alpha-blockers, dopamine agonist, diuretics, and/or vasodilators, abdominal compression, add salt and water to diet, water boluses, fludrocortisone, midodrine, droxidopa, pyridostigmine
Overactive bladder	Behavioral therapies (eg, bladder training, fluid management, pelvic floor muscle exercises), antimuscarinic agents, mirabegron, intradetrusor injections of botulinum toxin
Pain	Treatment as per type of pain (eg, dystonic, musculoskeletal, neuropathic), minimize “off” times, appropriate referral to orthopedics, physical therapy, pain specialist, rheumatology
REM sleep behavior disorder	Clonazepam, melatonin
Restless legs syndrome	Dopamine agonist at bedtime; gabapentin

FDA, Food and Drug Administration; GABA, γ-aminobutyric acid; PD, Parkinson disease; REM, rapid eye movement.

TREATMENT

Desired Outcomes

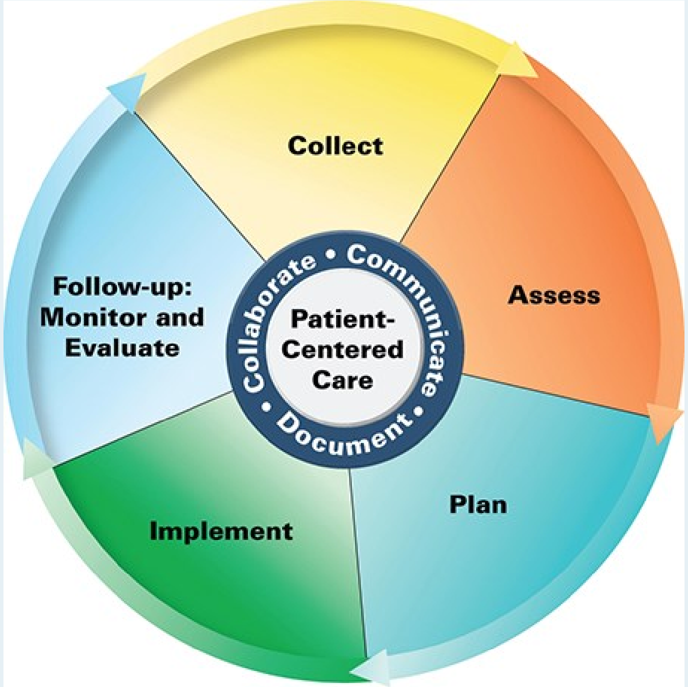
To date, no treatments effectively change the course of PD by slowing or halting its progression (disease modification).[25] Therefore, the goal for management is to improve motor and nonmotor symptoms so that patients are able to maintain the best possible quality of life.[26] Specific objectives to consider when selecting an intervention include preserving the ability to perform activities of daily living, employment, improvement of mobility, minimization of adverse effects, treatment complications, putative disease modification, and improvement of nonmotor features. To accomplish some of these objectives, consultation with a team of specialists is helpful (eg, movement disorders, pharmacotherapy, physical therapy, psychiatry, and sleep medicine).

General Approach to Treatment

① ② To optimize long-term therapeutic outcomes, minimize adverse effects, and improve quality of life for individuals with PD, clinicians need to (1) continually access motor and nonmotor symptoms, (2) thoughtfully consider initial and adjunctive therapies, and (3) continually adjust medication dosages throughout the course of this illness. Figure 78-4 illustrates a general treatment approach for early and advanced PD. Table 78-3 summarizes antiparkinsonian medications and dosing, and Table 78-4 summarizes monitoring parameters for potential adverse reactions, and Table 78-5 indicates place in therapy for antiparkinsonian medications (ie, monotherapy, adjunctive). Treatment guidelines and monographs are updated frequently to keep up with new information and changes in treatment paradigms.[24,27–30] Additionally, general guidelines and recommendations for geriatric health maintenance and disease prevention (eg, bone health, routine vaccinations, vitamin and mineral supplementations) should also be observed.

PATIENT CARE PROCESS

Patient Care Process for Parkinson Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, sex, hand dominance)

- Patient history (past medical, family, social—dietary habits, alcohol and tobacco use)
- Motor and nonmotor symptoms (see Tables 78-1 and 78-2)
- Current medications, prior medication use for PD and response to prior medications (eg, effectiveness, adverse effects), prior use of dopamine receptor blockers
- Objective data
    - Height, weight
    - Blood pressure and orthostatic blood pressure
    - Labs (eg, serum creatinine [Scr], liver function tests [LFTs])
    - Other diagnostic tests when indicated (eg, neuroimaging)

Assess

- Past and current use of medications associated with medication-induced parkinsonism (eg, antipsychotics, metoclopramide, tetrabenazine)
- Difficulties with performing activities of daily living
- Gait difficulties and fall risk
- Motor or nonmotor symptoms that are most troublesome for the patient
- Appropriateness, effectiveness, and adverse effects of current medications for the motor and nonmotor symptoms of PD
- Presence of motor complications (eg, motor fluctuations, dyskinesias, freezing)

Plan*

- Tailored lifestyle modifications (eg, exercise)
- Pharmacotherapy regimen including specific medications for PD, dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (see Table 78-3)
- Monitoring parameters including efficacy (eg, symptom improvement) and tolerability medication-specific adverse effects; see Table 78-4), and time frame
- Patient education (eg, purpose of treatment, lifestyle modification, pharmacotherapy, adverse effects)
- Self-monitoring of symptoms—where and how to record results
- Referrals to other providers when appropriate (eg, physician, physical therapy, speech therapy)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

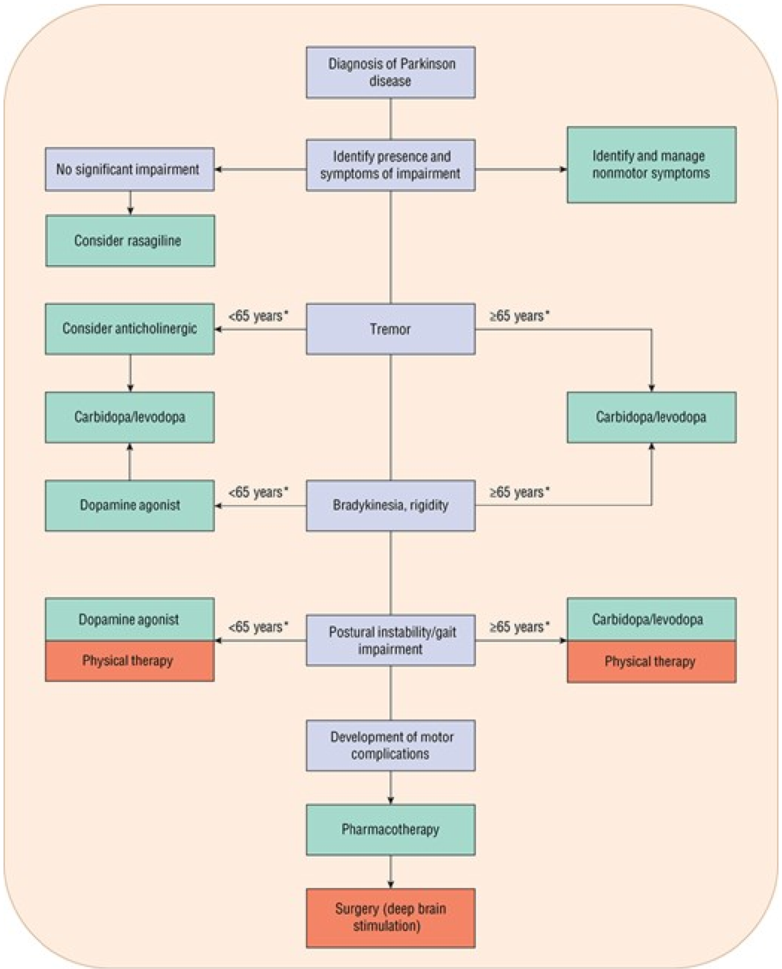
- Symptom relief goal attainment

- Presence of adverse effects
- Occurrence of motor complications, falls, and development/progression of nonmotor symptoms
- Patient adherence to treatment plan using multiple sources of information

Collaborate with patient, caregivers, and other healthcare professionals.[*]

FIGURE 78-4

General approach to the management of early to advanced Parkinson disease. (*Age is not the sole determinant for medication choice. Other factors such as cognitive function and overall medication tolerability, especially in older patients should be considered.)



Diagnosis of Parkinson disease
No significant impairment
Identify presence and symptoms of impairment
Identify and manage nonmotor symptoms
Consider rasagiline
Consider anticholinergic
<65 years*
Tremor
≥65 years*
Carbidopa/levodopa
Carbidopa/levodopa
Dopamine agonist
<65 years*
Bradykinesia, rigidity
≥65 years*
Dopamine agonist
Physical therapy
<65 years*
Postural instability/gait impairment
≥65 years*
Carbidopa/levodopa
Physical therapy
Development of motor complications
Pharmacotherapy
Surgery (deep brain stimulation)

TABLE 78-3

Dosing of Medications Used in Parkinson Disease[a]

Generic Name	Trade Name	Starting Dose[b] (mg/day)	Maintenance Dose[b] (mg/day)	Dosage Forms (mg)
Adenosine-Receptor Antagonist				

Istradefylline	Nourianz	20	20-40	20, 40
Anticholinergic Medications				
Benztropine	Cogentin	0.5-1	1-6	0.5, 1, 2
Trihexyphenidyl	Artane	1-2	6-15	2, 5, 2/5 mL
Carbidopa/Levodopa Products				
Carbidopa/L-dopa	Sinemet	300[c]	300-2,000[c]	10/100, 25/100, 25/250
Carbidopa/L-dopa ODT	Parcopa	300[c]	300-2,000[c]	10/100, 25/100, 25/250
Carbidopa/L-dopa CR	Sinemet CR	400[c]	400-2,000[c]	25/100, 50/200
Carbidopa/L-dopa IR/ER	Rytary	435[c]	435-2,450[c]	23.75/95, 36.25/145, 48.75/195, 61.25/245[d]
Carbidopa/L-dopa enteral suspension	Duopa	1,000[c]	1,000-2,000[c]	4.63/20 per mL
Carbidopa/L-dopa/entacapone	Stalevo	600[e]	600-1,600[e]	12.5/50/200, 18.75/75/200, 25/100/200, 31.25/125/200, 37.5/150/200, 50/200/200
Carbidopa	Lodosyn	25	25-75	25
Levodopa	Inbrija	84	84-420	42[f]
Dopamine Agonists				
Apomorphine	Apokyn	1-3	3-12	30/3 mL[g]
Apomorphine	Kynmobi	10	10-150	10, 15, 20, 25, 30[h]
Bromocriptine	Parlodel	2.5-5	15-40	2.5, 5
Pramipexole	Mirapex	0.125	1.5-4.5	0.125, 0.25, 0.5, 0.75, 1, 1.5
Pramipexole ER	Mirapex ER	0.375	1.5-4.5	0.375, 0.75, 1.5, 2.25, 3, 3.75, 4.5
Ropinirole	Requip	0.75	9-24	0.25, 0.5, 1, 2, 3, 4, 5
Ropinirole XL	Requip XL	2	8-24	2, 4, 6, 8, 12
Rotigotine	Neupro	2	2-8	1, 2, 3, 4, 6, 8
COMT Inhibitors				
Entacapone	Comtan	200-600	200-1,600	200

Opicapone	Ongentys	25-50	50	25, 50
Tolcapone	Tasmar	300	300-600	100, 200
MAO-B Inhibitors				
Rasagiline	Azilect	0.5-1	0.5-1	0.5, 1
Safinamide	Xadago	50	50-100	50, 100
Selegiline	Eldepryl	5-10	5-10	5
Selegiline ODT	Zelapar	1.25	1.25-2.5	1.25, 2.5
Miscellaneous				
Amantadine	Symmetrel	100	200-300	100, 50/5 mL
Amantadine ER	Gocovri	137	274	68.5, 137
Amantadine ER	Osmolex	129	129-258	129, 193, 258

COMT, catechol-*O*-methyltransferase; CR, controlled-release; IR, immediate-release; ER, extended-release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.

[a] Marketed in the United States for Parkinson disease.

[b] Dosages may vary.

[c] Dosages expressed as L-dopa component.

[d] Dosages of Rytary were developed to avoid confusion with other oral carbidopa/L-dopa products that contain L-dopa in multiples of 50 mg.

[e] Dosages expressed as entacapone component.

[f] Capsule containing levodopa dry powder for inhalation.

[g] Sterile solution of subcutaneous injection with supplied pen injector.

[h] Sublingual film of apomorphine.

Data from Reference [31].

TABLE 78-4

Monitoring of Potential Adverse Reactions to Pharmacotherapy for Parkinson Disease

Generic Name	Adverse Medication Reaction	Monitoring Parameter	Comments
Amantadine	- Confusion - Livedo reticularis	Mental status; renal function Lower	Reduce dosage; adjust dose for renal impairment Reversible upon medication discontinuation

		extremity examination; ankle edema	
	Livedo reticularis	Lower extremity examination; ankle edema	Reversible upon medication discontinuation
Benztropine and Trihexyphenidyl	Anticholinergic effects, confusion, drowsiness	Dry mouth, mental status, constipation, urinary retention, vision	Reduce dosage; avoid in elderly and in those with a history of constipation, memory impairment, urinary retention
Carbidopa/L-dopa	• Drowsiness • Dyskinesias • Nausea	• Mental status • Abnormal involuntary movements • Nausea	• Reduce dose • Reduce dose; add amantadine • Take with food (eg, nonprotein snack)
Istradefylline	Insomnia, dizziness, nausea, constipation	Sleep, nausea, bowel movements	• Take in the morning • Take with food
COMT Inhibitors			
Entacapone	Augmentation of L-dopa adverse effects; also diarrhea	See carbidopa/L-dopa; also bowel movements	Reduce dose of L-dopa; antidiarrheal agents
Opicapone	Augmentation of L-dopa adverse effects, constipation	Mental status, abnormal involuntary movements, bowel movements	Reduce dose of L-dopa
Tolcapone	See entacapone; also liver toxicity	See carbidopa/L-dopa; also ALT/AST	See carbidopa/L-dopa; also at start of therapy and for every dose increase, ALT and AST levels at baseline and every 2-4 weeks for the first 6 months of therapy; afterward monitor based on clinical judgment.
Dopamine Agonists			
Apomorphine	• Drowsiness • Nausea • Orthostatic hypotension	• Mental status • Nausea • Blood pressure, dizziness upon standing	• Reduce dose • Premedicate with trimethobenzamide • Reduce dose
Bromocriptine	See pramipexole; also pulmonary fibrosis	Mental status; also chest radiograph	Reduce dose; chest radiograph at baseline and once yearly
Pramipexole and Ropinirole	• Confusion • Drowsiness • Edema • Hallucinations/delusions	• Mental status • Lower extremity swelling • Behavior, mental	• Reduce dose • Reduce dose or discontinue medication • Reduce dose or discontinue medication • Titrate dose upward slowly; take with food

	- Impulsivity - Nausea - Orthostatic hypotension	status - Nausea - Blood pressure, dizziness upon standing	
Rotigotine	See pramipexole; also skin irritation at site of patch application	See pramipexole; also skin examination	See pramipexole; rotate patch application site
MAO-B Inhibitors			
Rasagiline	Nausea	Nausea	Take with food
Safinamide	- Nausea - Elevation in blood pressure Insomnia	- Nausea - Blood pressure Sleep	- Take with food - Monitor blood pressure if have a history of uncontrolled hypertension - Take in the morning
Selegiline	- Agitation/confusion - Insomnia - Hallucinations - Orthostatic hypotension	- Mental status - Sleep - behavior, mental status - Blood pressure, dizziness upon standing	- Reduce dose - Administer dose earlier in day - Reduce dose - Reduce dose

ALT, alanine aminotransferase; AST, aspartate aminotransferase; COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase.

When deciding on therapy for a patient, the following patient-specific factors should be taken into account: age; comorbidities; severity of functional impairment; nonmotor symptoms; patient preferences, therapeutic goals, and outcomes; employment status; medication tolerability; presence of cognitive impairment or motor complications; need for skilled assistance; and health-related economics.[30] The lowest dose of antiparkinsonian medication that provides satisfactory symptomatic results should be used, and for patients already on carbidopa/levodopa (L-dopa), optimization of the regimen should be attempted before adding adjunctive agents (see Table 78-5 for which agents may be used as monotherapy, on demand therapy, and adjunctive therapy) . With the increasing motor disability, emergence of medication adverse effects, and changes in severity of nonmotor symptoms, therapy adjustments (eg, dose reductions, medication addition, or discontinuation) are expected, and desired therapeutic endpoints should be routinely reassessed. There are no pharmacogenomic parameters used to guide PD pharmacotherapy.

For mild functional impairment, initial monotherapy may be initiated with an MAO-B inhibitor, such as rasagiline, with the addition of other therapeutic agents as PD motor symptoms progressively worsen. Dopamine agonist monotherapy provides greater symptomatic benefit for patients with mild-to-moderate impairment. However, dopamine agonists are less well tolerated, especially in older patients and for those who are cognitively impaired, intolerant of dopamine agonists, or experiencing moderate or severe functional impairment, carbidopa/L-dopa is preferred.[28–30] Ultimately, all patients will require the use of carbidopa/L-dopa either as monotherapy or in combination with other agents. With the development of motor fluctuations, patients should administer carbidopa/L-dopa more frequently or addition of a catechol-*O*-methyltransferase (COMT) inhibitor, MAO-B inhibitor, A2AR antagonist, or dopamine agonist to the carbidopa/L-dopa regimen should be considered. For management of carbidopa/L-dopa–induced peak-dose dyskinesias, a reduction in L-dopa dose and/or addition of amantadine should be considered. Surgery is considered only in patients who need more symptomatic control or who are experiencing severe motor complications despite pharmacologically optimized therapy.

Ultimately, the treatment plan must evolve as the disease progresses and must include consideration of short-term symptomatic relief as well as long-term effects. Patient education should be communicated with realistic optimism. For example, although there is no cure for PD, medications that can provide relief of symptoms. Nonpharmacologic interventions such as exercise should be encouraged, and problematic nonmotor features of PD should always be addressed.

TABLE 78-5

Summary of Medications for Parkinson Disease Regarding Type: Monotherapy, Adjunctive, and/or On-Demand Options Summary of Medications for Parkinson Disease Regarding Type: Monotherapy, Adjunctive, and/or On-Demand Options

Medication	Class	Monotherapy	Adjunctive	On-Demand
Amantadine	NMDA receptor antagonist	X (rarely)	X	
Apomorphine	Dopamine agonist			X
Benztropine	Anticholinergic	X	X	
Carbidopa	Decarboxylase inhibitor		X[a]	
Entacapone	COMT inhibitor		X[a]	
Istradefylline	Adenosine-receptor antagonist		X	
Levodopa	Dopamine precursor	X	X	X
Opicapone	COMT inhibitor		X[a]	
Pramipexole	Dopamine agonist	X	X	
Rasagiline	MAO-B inhibitor	X	X	
Ropinirole	Dopamine agonist	X	X	
Rotigotine	Dopamine agonist	X	X	
Safinamide	MAO-B inhibitor	X	X	
Selegeline	MAO-B inhibitor		X	
Tolcapone	COMT inhibitor		X[a]	
Trihexyphenidyl	Anticholinergic	X	X	

Of note, table is based upon FDA-approved indications. Some agents may be used off-label as monotherapy/adjunct.

[a] Must be used in combination with Levodopa.

Nonpharmacologic Therapy

A number of nonpharmacological modalities may help improve motor and non-motor symptoms of PD in combination with appropriate pharmacotherapy. Exercise, physiotherapy, yoga, Tai Chi, and dance have evidence to support improvement in PD symptoms.[32] A specific form of physiotherapy that patients with PD may particularly benefit from is the Lee Silvermann Voice Treatment-BIG Therapy. This therapy focuses on increasing the amplitude of movements by focusing on proprioception using sensory cues.[33]

Surgical Therapy

3 Surgery should be considered an adjunct to pharmacotherapy when patients are experiencing frequent motor fluctuations or disabling dyskinesia or tremor despite an optimized medical regimen. There are several patient-selection criteria for surgery, including a diagnosis of L-dopa–responsive PD and absence of cognitive impairment. Anatomic targets include the thalamus, GPi, and the STN. Bilateral, chronic, high-frequency electrical stimulation, also known as deep-brain stimulation (DBS), is the preferred surgical modality.[34]

In DBS surgery, a battery-powered neurostimulator is implanted subcutaneously below the clavicle and provides constant electrical stimulation, via electrode wires, to the targeted brain structure. Thalamic DBS is effective for suppressing tremor (specifically arm tremor), but it does not significantly improve the other parkinsonian features (bradykinesia, rigidity, motor fluctuations, or dyskinesias). Both STN and GPi DBS are associated with improvements in tremor, rigidity, bradykinesia, motor fluctuations, dyskinesia, and activities of daily living; however, STN DBS allows for greater reduction in medications.[35] As with pharmacotherapy, DBS uncommonly improves gait or postural instability.

DBS procedures require routine adjustment of the electrical stimulation parameters (eg, voltage, frequency, and pulse width) to achieve optimal control while minimizing adverse effects. The electrical stimulation parameters (or “electrical dosage”) are adjusted via a programmable handheld device to meet each patient’s needs and are performed by physicians as well as other trained individuals, including nurse practitioners and clinical pharmacists.

Pharmacologic Therapy

Anticholinergic Medications

4 Dopamine provides negative feedback to acetylcholine neurons in the striatum; therefore, degeneration of nigrostriatal dopamine neurons affects striatal cholinergic interneuron activity. Recent research investigated the effect of dopamine loss on the striatal interneurons in mice models. Initially, the striatal interneurons decreased acetylcholine production slightly, but with the even greater loss of dopamine (which occurs throughout the progression of PD), the balance among the two neurotransmitters shifted to greater acetylcholine levels.[36] This increased cholinergic activity is believed to contribute to the tremor of PD. The anticholinergic medications (eg, benztropine and trihexyphenidyl) are considered effective against tremor, but no more so than dopaminergic agents.[28] Sometimes dystonic symptoms associated with PD are also improved by anticholinergic agents. Use of anticholinergic agents is limited due to the development of intolerable anticholinergic adverse effects (see Table 78-4), necessitating medication discontinuation. Younger patients are better able to tolerate anticholinergic adverse effects, whereas this medication class is avoided in patients with advanced age, pre-existing cognitive deficits, and dysphagia.[37,38]

Amantadine

5 Although amantadine can be used as monotherapy for the management of tremor, rigidity, and bradykinesia, it is most often used adjunctively for management of L-dopa–induced dyskinesia and in patients experiencing “off” episodes[28,29,39] (Table 78-3). The precise mechanism of action of amantadine for management of PD is unknown, but enhancement of dopamine release from presynaptic terminals and inhibition of glutamatergic *N*-methyl-D-aspartate (NMDA) receptors are implicated.[40] The antidyskinetic properties of amantadine are presumed to be mediated by antiglutamate properties which, in the setting of dyskinesias, dominate over dopaminergic properties. There are currently three different formulations of amantadine available for use; an immediate release (IR) formulation and two different extended release (ER) products. Amantadine immediate-release is typically administered 300 mg/day in divided doses whereas the extended-release formulations allow for once a day dosing (see Table 78-3).[41] Amantadine is eliminated renally, and a reduced dose should be administered when renal dysfunction is present (eg, amantadine immediate-release 100 mg/day with creatinine clearances of 30-50 mL/min [0.50-0.84 mL/s], 100 mg every other day for creatinine clearances of 15-29 mL/min [0.25-0.49 mL/s], and 200 mg every 7 days for creatinine clearances of less than 15 mL/min [0.25 mL/s], and patients on hemodialysis).[42]

Adverse effects of amantadine include confusion, dizziness, dry mouth, and hallucinations with elderly patients being particularly prone to develop confusion.[43,44] Not uncommonly, amantadine may cause livedo reticularis, a reversible condition characterized by diffuse mottling of the skin affecting the upper or lower extremities and often accompanied by lower-extremity edema (see Table 78-4).[45,46]

Carbidopa/L-Dopa

6 L-Dopa is the immediate precursor of dopamine and, in combination with a peripherally acting L-amino acid decarboxylase inhibitor (carbidopa or benserazide), remains the most effective medication for the symptomatic treatment of PD.[28,29] In the United States, L-Dopa is combined with carbidopa as L-Dopa crosses the blood–brain barrier, whereas carbidopa does not, and the carbidopa then reduces the unwanted peripheral conversion of L-dopa to dopamine. As a result, increased amounts of L-dopa are transported into the brain, and the peripheral adverse effects of dopamine, such as nausea, are reduced. In the SNc, L-dopa is converted to dopamine by the enzyme L-amino acid decarboxylase and inactivated by the enzymes MAO and COMT (Figs. 76-1 and 76-5).

FIGURE 78-5

Dopamine synthesis and metabolism within the striatal neurons. See also Fig. 78-1 for additional details. (COMT, catechol-*O*-methyltransferase; D_1-D_2, dopamine receptors; L-AAD, L-aromatic amino acid decarboxylase; L-Dopa, levodopa; MAO-B, monoamine oxidase B.)

6 Regardless of what the initial therapeutic agent is, ultimately all patients with PD will require L-dopa. Regarding carbidopa, about 75 mg/day is required to sufficiently inhibit the peripheral activity of L-amino acid decarboxylase, but some patients require more.[47] Therefore, the usual initial maintenance carbidopa/L-dopa regimen is 25/100 mg three times daily. As the motor features of PD become progressively more severe, use of higher dosages is required. There is no maximum allowable total daily L-dopa dose; however, in patients with severe PD, the usual maximal dose tolerated is approximately 1,000 to 1,500 mg/day. Slow buildup of dose (eg, increments of 100 mg L-dopa per week) can help minimize treatment-emergent adverse effects, such as drowsiness and nausea (see Table 78-4).

Various formulations of carbidopa/L-dopa are available (see Table 78-3). For patients with difficulty swallowing intact tablets, an orally disintegrating tablet (ODT) preparation of carbidopa/L-dopa is available, and while this formulation rapidly dissolves on contact with saliva, the carbidopa/L-dopa does not undergo transmucosal absorption, and the dissolved medication in saliva must be swallowed for absorption in the proximal duodenum. Additionally, carbidopa/L-dopa is available in an oral capsule formulation containing immediate-release (IR) and extended-release (ER) beads (ie, Rytary) which can be sprinkled on food (eg, apple sauce).

Pharmacokinetics

There is marked intra- and intersubject variability in the time to peak plasma concentrations after oral carbidopa/L-dopa. This may in part be attributed to differences in gastric emptying as L-Dopa is absorbed in the proximal duodenum by a saturable large neutral amino acid transport system.[48] Therefore, competition for this transporter by large dietary, or pharmaceutical, neutral amino acids (eg, leucine, phenylalanine) may result in reduced L-dopa bioavailability. However, for patients with early PD, this interaction is generally not significant.

L-Dopa is not bound to plasma proteins and is actively transported across the blood–brain barrier by the large neutral amino acid transporter system. In advanced PD, special diets involving protein restriction may improve L-dopa responsiveness and are sometimes implemented. A metabolite of L-dopa, 3-*O*-methyldopa also competes for transport, but it is not clear how this affects L-dopa clinical response.

When peripheral decarboxylation of L-dopa is inhibited by carbidopa, 3-*O*-methylation (via COMT) becomes the predominant catabolic pathway. The elimination half-life of L-dopa is about 1 hour, and this is extended to about 1.5 hours with the addition of carbidopa. With the addition of a COMT inhibitor such as entacapone to carbidopa/L-dopa, the elimination half-life is extended to about 2 to 2.5 hours.

The controlled-release (ie, Sinemet CR) and IR/ER carbidopa/L-dopa formulations (ie, Rytary) are 70% and 75% bioavailable, respectively, compared to standard IR carbidopa/L-dopa.[49] Manufacturer-provided dosage conversion recommendations are available to guide dosing conversions between carbidopa/L-dopa formulations.

Motor Complications of L-Dopa

⑦ Long-term L-dopa therapy is associated with a variety of motor complications, of which end-of-dose “wearing off” (motor fluctuations) and L-dopa peak-dose dyskinesias are the two most encountered.[50] These motor complications can become disabling and a challenge to manage. Risk factors associated with the development of motor complications include higher dosages of L-dopa and a younger age of PD onset.[51,52] The 5-year cumulative incidence of motor complications is about 50% in a medication naïve population.[53] Table 78-6 lists the common motor complications associated with long-term treatment with L-dopa and suggested initial management strategies. Initiating therapy with the controlled release (CR) form of carbidopa/L-dopa (ie, Sinemet CR) does not reduce the development of motor complications compared with IR carbidopa/L-dopa.[28]

TABLE 78-6

Common Motor Complications and Possible Initial Treatments

Effects	Possible Treatments
End-of-dose “wearing off” (motor fluctuation)	Increase frequency of carbidopa/L-dopa doses; add either COMT inhibitor or MAO-B inhibitor or dopamine agonist; add or switch to extended-release carbidopa/L-dopa (ie, Rytary); use L-dopa inhalation or apomorphine subcutaneous or sublingual
“Delayed on” or “no on” response	Give carbidopa/L-dopa on empty stomach; use carbidopa/L-dopa ODT; avoid carbidopa/L-dopa SR; use apomorphine subcutaneous or sublingual or L-dopa inhalation
Start hesitation (“freezing”)	Increase carbidopa/L-dopa dose; add a dopamine agonist or MAO-B inhibitor; utilize physical therapy along with assistive walking devices or sensory cues (eg, rhythmic commands, stepping over objects)
Peak-dose dyskinesia	Provide smaller doses of carbidopa/L-dopa at the same or increased dosing frequency; reduce dose of adjunctive dopamine agonist; add amantadine

COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase; ODT, orally disintegrating tablet; SR, sustained release.

End-of-Dose “Wearing Off”

⑦ The terms “off” and “on” refer to periods of poor movement (ie, return of tremor, rigidity, or slowness) and good movement, respectively. End-of-dose “wearing off” prior to the next dose of medication is a common type of response fluctuation. This phenomenon is related to the increasing loss of neuronal storage capability for dopamine as well as the short half-life of L-dopa.[54] Initially, exogenous L-dopa is taken up by the remaining SNc neurons, converted to dopamine and stored in synaptic vesicles. With progressive loss of SNc neurons and storage capacity, patients become more dependent on exogenous carbidopa/L-dopa. Hence, the peripheral pharmacokinetic properties of L-dopa increasingly become the determinant of central dopamine synthesis. With advancing PD, the duration of action of a single carbidopa/L-dopa dose progressively shortens and in some cases may produce benefits for as little as 1 hour. As a result, carbidopa/L-dopa needs to be given more frequently, although other options are also available (see Table 78-6). In particular, the addition of the COMT inhibitor entacapone or an MAO-B inhibitor (ie, rasagiline, safinamide), or zonisamide (off-label use in the US) extends the action of L-dopa and should be considered.[28] A dopamine agonist (eg, pramipexole, ropinirole, or rotigotine) can also be added to a carbidopa/L-dopa regimen for the management of “wearing off.” The older CR L-dopa product (ie, Sinemet CR) has been investigated for the management of motor fluctuations, but the evidence is not compelling.[28] A newer IR/ER carbidopa/L-dopa formulation (ie, Rytary) contains beads that dissolve at different rates. Following administration, therapeutic L-dopa levels are rapidly achieved and are maintained for 4 to 5 hours providing efficacy for the management of motor fluctuations.[55] Clinical trials are currently underway investigating another IR/ER carbidopa/L-dopa formulation, which aims to further a steadier L-dopa level.[56]

Carbidopa/L-dopa enteral suspension is effective and safe for patients with advanced PD experiencing persistent, on/off fluctuations.[57] This enteral suspension is contained within a medication cassette reservoir and infusion into the small intestine is achieved by a portable pump device which requires placement of a percutaneous endoscopic gastrostomy tube along with a jejunal extension, through the abdominal wall. The medication infusion typically runs for 16 continuous hours per day and is turned off at night.

Less-invasive deliveries of carbidopa/L-dopa to minimize motor fluctuations are currently being investigated in clinical trials. ND0612 is a self-administered subcutaneous infusion of carbidopa/L-dopa currently in phase III trials. ABBV-951 is another subcutaneous infusion of carbidopa/L-dopa also in phase III clinical trials.[58]

For rapid relief of acute off episodes, apomorphine (available as either a subcutaneously or sublingually administered short-acting dopamine agonist) or a L-dopa dry powder for inhalation may be administered as needed.[59,60] Although not commonly performed, sipping small amounts of carbidopa/L-dopa solution frequently throughout the day is also a method for managing on/off fluctuations. A solution that is stable for 72 hours at room temperature can be prepared by adding 10 crushed tablets of carbidopa/L-dopa 10/100 (or 25/100) mg and 2 g crystalline ascorbic acid to 1 L of water.[61]

Often though, off episodes occur during the night, and patients will awaken in an off state because of an overnight decline of medication levels. Therefore, bedtime administration of a dopamine agonist or a medication formulation that provides sustained medication levels overnight (eg, carbidopa/L-dopa CR or IR/ER, ropinirole XL, pramipexole ER, rotigotine transdermal patch) can help reduce nocturnal off episodes and improve functioning upon awakening.

Nonadherence to medications also contributes to the frequency of off episodes. Therefore, engaging and supporting patients and caregivers in overcoming barriers to medication adherence is important.

"Delayed-On" or "No-On" Response

"Delayed-on" or "no-on" responses describe a delayed or absent onset of medication effect to individual doses of carbidopa/L-dopa which can be a result of delayed gastric emptying or decreased duodenum absorption. To overcome this effect, chewing a tablet or crushing it and then drinking a full glass of water or using the ODT formulation on an empty stomach can help mitigate effects of delayed gastric emptying. Alternatively, the use of the inhaled L-dopa bypasses the gastrointestinal (GI) tract to provide systemic absorption and help induce "on" time for patients.[62] Additionally, subcutaneously or sublingually administered apomorphine may be used as on-demand therapy for delayed-on or no-on periods.[62]

Freezing

"Freezing," or a sudden, episodic akinesia (lack of movement) of the lower extremities, is an event described by patients as a feeling where their "feet suddenly feel stuck to the floor" during ambulation or they have difficulty initiating steps (start hesitation) or turns (turn hesitation). As freezing often is exacerbated by anxiety or when perceived obstacles (eg, doorways, turnstiles) are encountered, this event may interfere with ambulation and increase the risk of falls. In addition to optimal pharmacological management, physical therapy and use of assistive walking devices and sensory cues aid in the reduction of "freezing" episodes.[63]

Dykinesias

⑨ Another complication of L-dopa therapy is "on" period dyskinesias that are involuntary choreiform movements usually involving the neck, trunk, and lower/upper extremities. Dyskinesias are specific to L-dopa therapy and if patients report "shakiness," it is important to clarify if they are referring to tremor or dyskinesias. To help differentiate the two, it is important to note that dyskinesias are usually associated with peak striatal dopamine levels (peak-dose dyskinesia) and, simplistically, can be thought of as too much movement secondary to extension of the L-dopa pharmacologic effect.[64] Lowering the dose of carbidopa/L-dopa to counteract dyskinesias should be attempted. However, the use of a lower dose may result in suboptimal control of parkinsonian features; thus, necessitating addition of another antiparkinsonian agent (eg, dopamine agonist). Another strategy is to lower the individual dose of L-dopa, but administer more frequently. Glutamate overactivity may also be involved, as suggested by the dyskinesia improvement observed with amantadine (NMDA-receptor antagonist) and other antiglutamate ligands.[65] Less commonly, dyskinesias also can develop during the rise and fall of L-dopa effects (the dyskinesia–improvement–dyskinesia or diphasic pattern of response). For severe dyskinesias (despite pharmacologically optimized therapy), surgery should be considered.

"Off-Period" Dystonia

In PD, dystonias are sustained muscle contractions that can occur and more commonly affect a distal lower extremity (eg, clenching of toes or involuntary turning of a foot). Dystonias often occur in the early morning hours, due to waning medication levels, and improve with the first carbidopa/L-dopa dose of the day. Remedies for early morning dystonia include bedtime administration of a long-acting dopamine agonist, long-acting carbidopa/L-dopa, or baclofen. Additionally, focal injections of botulinum toxin type A or B are effective for persistent focal dystonias, which can also occur as L-dopa peak dose effect; therefore, additional management of this specific adverse event is similar to that of dyskinesias.[66]

Adenosine Receptor Antagonist

One of the newest FDA approved agents for the adjunctive treatment of PD is the xanthine derivative, istradefylline, an adenosine A2AR antagonist. This non-dopaminergic medication is theorized to exert its effect by antagonizing the adenosine A2AR in the indirect movement pathway.[16] Patients with PD have been found to have an increase in adenosine A2ARs.[67] Adenosine increases the activation of the indirect pathway, further inhibiting movement. Antagonizing the A2AR therefore allows for decreased activation of the indirect pathway and may allow for an increase in movement.

Istradefylline is currently approved as an adjunctive treatment to L-dopa for patients with “off” episodes. It is generally well tolerated with the most common adverse effects including insomnia, hallucination, nausea, and constipation. The pharmacokinetics of istradefylline include metabolism primarily by cytochrome P450 (CYP450) CYP1A1 and CYP3A4 with an elimination half-life of approximately 80 hours.[68] It is recommended to avoid use in the presence of a strong CYP3A4 inducer and to reduce the dose when co-administered with a strong CYP3A4 inhibitor. The recommended starting dose is 20 mg daily, which can be increased to 40 mg daily. In patients who smoke more than 20 cigarettes a day (or equivalent tobacco product), the recommended dose is 40 mg per day.[68]

Monoamine Oxidase B Inhibitors

⑤ Three selective MAO-B inhibitors (rasagiline, safinamide, selegiline) are available for management of PD (see Table 78-3). The selective inhibition of MAO-B in the brain interferes with the degradation of dopamine and results in prolonged dopaminergic activity. Rasagiline and selegiline contain a propargylamine moiety, which is essential for conferring irreversible inhibition of MAO-B, in contrast to safinamide, which is a reversible MAO-B inhibitor.[69] At therapeutic doses, all three agents preferentially inhibit MAO-B over MAO-A.

A common concern with use of these agents is the potential for interactions with medications that possess serotonergic activity. Concomitant use of MAO-B inhibitors with meperidine and other selected opioid analgesics is contraindicated because of a small risk of serotonin syndrome. However, serotonergic antidepressants can be used concomitantly when clinically warranted, as these are not contraindicated.[70]

MAO-B inhibitors have also been investigated for neuroprotective properties (clinically referred to as *disease modification*). MAO-B inhibitors possess antiapoptotic properties, and MAO-B inhibition diverts dopamine degradation to an alternate route (ie, COMT) that does not generate free radicals (see Figs. 76-1 and 76-5).[71] To date, clinical studies to demonstrate disease modification with MAO-B inhibitors have yielded inconclusive results.[72–74]

⑤ ⑧ Selegiline, also known as L-deprenyl, is marketed for extending L-dopa effects and is typically administered 5 mg twice daily. Selegiline is also available as an ODT formulation administered 1.25 to 2.5 mg once daily, and a transdermal formulation which is not indicated for PD. As monotherapy in early PD, selegiline provides modest improvements in motor function.[74] In advanced PD, adjunctive use of selegiline can provide up to 1 hour of extra “on” time for patients with “wearing off,” although the data are inconsistent,[28] which may be explained, in part, by the poor and erratic bioavailability of selegiline.

As an amphetamine pharmacophore, selegiline undergoes first-pass hepatic metabolism, predominantly via CYP2B6 and 2C19, to end products of L-methamphetamine and L-amphetamine.[75] Adverse effects of selegiline are minimal but can include agitation, insomnia (especially if administered at bedtime), hallucinations, and orthostatic hypotension (see Table 78-4). Selegiline also increases the peak effects of L-dopa and can worsen pre-existing dyskinesias or psychiatric symptoms such as delusions. With the selegiline ODT formulation, first-pass hepatic metabolism is bypassed as a consequence of transmucosal absorption; hence, bioavailability is improved and formation of amphetamine metabolites is reduced.

⑤ ⑧ Rasagiline is a second-generation, irreversible, selective MAO-B inhibitor administered at 0.5 or 1 mg once daily, which is effective as monotherapy in early PD. It is also effective as add-on therapy for managing motor fluctuations in advanced PD with efficacy similar to that of entacapone, offering approximately 1 hour of extra “on” time during the day.[28] Rasagiline is well tolerated with minimal GI or neuropsychiatric adverse effects and is metabolized by CYP1A2 to aminoindan, which is inactive and devoid of amphetamine-like properties.[76]

⑤ ⑧ Safinamide is a reversible, selective MAO-B inhibitor administered at 50 or 100 mg once daily indicated as add-on therapy to carbidopa/L-dopa for managing motor fluctuations and provides up to 1 hour of extra “on” time during the day.[28] Nondopaminergic effects include state-dependent inhibition of voltage-gated sodium channels and modulation of release of glutamate.[77] However, the extent to which these properties of safinamide contribute to the overall medication effect is unclear. Safinamide is well tolerated with minimal GI or neuropsychiatric adverse effects and is predominantly metabolized by nonmicrosomal enzymes (cytosolic amidases) to inactive metabolites which are excreted renally.[77]

Catechol-*O*-Methyltransferase Inhibitors

8 Three COMT inhibitors, entacapone, opicapone, and tolcapone, have been developed to extend the effects of L-dopa and are indicated for managing "wearing off". Mechanistically, all reduce the peripheral conversion of L-dopa to dopamine, thus enhancing central L-dopa bioavailability. Consequently, in the absence of L-dopa, they have no effect on PD symptoms. COMT inhibitors increase L-dopa area under the curve by approximately 35% and, for patients with "wearing off," can increase "on" time by about 1 to 2 hours.[28,78]

Tolcapone inhibits both peripheral and central COMT, but its use is limited by reports of fatal hepatotoxicity, such that strict monitoring of hepatic function, especially during the first 6 months of therapy, is required (see Table 78-4). Because of this risk, it is reserved for patients with fluctuations that are not responding to other therapies.[79]

Entacapone has a shorter half-life than tolcapone, and 200 mg needs to be given with each dose of carbidopa/L-dopa up to a maximum of eight times per day. A triple-combination product of carbidopa/L-dopa/entacapone offers convenience for some patients (ie, fewer tablets to administer). Unlike tolcapone, entacapone is not associated with hepatotoxicity; therefore, it is considered efficacious and clinically useful as adjunctive therapy to manage motor fluctuations.[28]

Opicapone is a third-generation COMT inhibitor that selectively blocks the peripheral conversion of L-dopa. Its long duration of action compared to entacapone and tolcapone allows for once-a-day dosing.[80] Opicapone 50 mg once daily at bedtime is the recommended dose for most patients and 25 mg daily for patients with moderate hepatic impairment. The mean "off" time reduction in clinical trials for opicapone has been greater than that for entacapone, suggesting a more robust clinical response.[81]

With all agents, augmentation of dopaminergic adverse effects may occur and generally are manageable by reduction of the carbidopa/L-dopa dosage. Patients should be advised that other adverse effects include brownish-orange urinary discoloration and diarrhea occurring weeks to months after treatment initiation may occur with the use of entacapone or tolcapone.

Dopamine Agonists

Dopamine agonists fall into two pharmacologic subtypes: ergot-derived agonists (bromocriptine) and the non-ergot agonists (apomorphine, pramipexole, ropinirole, and rotigotine).[82] Non-ergot agonists have a better safety profile and are more commonly used than the ergot-derived agonists. Pharmacologically dopamine agonists stimulate dopamine receptors (eg, D_1, D_2, D_3) and are useful as monotherapy in mild-to-moderate PD and also as adjuncts to carbidopa/L-dopa therapy to reduce "off" time in patients with motor fluctuations.[28]

10 Compared with long-term carbidopa/L-dopa therapy, dopamine agonist significantly reduce the risk of developing motor complications.[83,84] For younger patients, who are more likely to develop motor complications, dopamine agonists are preferred over carbidopa/L-dopa. For older patients, dopamine agonists should be used conservatively due to greater likelihood for the development of intolerable adverse effects and for patients with cognitive problems or dementia, dopamine agonists should be avoided.

Common adverse effects of dopamine agonists include nausea, confusion, drowsiness, hallucinations, lower-extremity edema, and orthostatic hypotension (see Table 78-4).[85] When initiating therapy, a slow dose titration is required to minimize development of adverse effects, particularly nausea. The addition of a dopamine agonist to carbidopa/L-dopa therapy also can induce dyskinesias, especially in patients with pre-existing dyskinesias. Less common but serious adverse effects include impulsive and compulsive behaviors (eg, pathologic gambling or shopping; paraphilia), delusions/psychosis, and sleep attacks (sudden, unexpected episodes of sleep). Hallucinations and delusion should be managed using a systematic approach that starts with dose reduction or discontinuation of the dopamine agonist, and if needed, addition of a second-generation antipsychotic medication such as clozapine, pimavanserin, or quetiapine.[24,30,86] Of these, only pimavanserin is FDA-approved for psychosis in PD. Involvement of caregivers in surveillance for potential adverse effects of dopamine agonists, particularly development of delusions, hallucinations, and impulsive behaviors, facilitates earlier detection and management.

Apomorphine is an aporphine alkaloid originally derived from morphine that lacks narcotic properties.[59] It exhibits poor oral bioavailability due to extensive hepatic first-pass metabolism and is administered either sublingually or subcutaneously. Apomorphine is indicated for patients with advanced PD who are experiencing intermittent "off" episodes despite optimized therapy. Upon subcutaneous administration, apomorphine produces an "on" response within 20 minutes. The effective dose ranges from 2 to 6 mg per injection. Sites of injection (abdomen, upper arm, and upper thigh) should be rotated to avoid development of subcutaneous nodules. The elimination half-life for subcutaneous apomorphine is approximately 40 minutes, and the duration of benefit can be up to 100 minutes.[87] In comparison, the sublingual dosage form of apomorphine typically takes about 30 to 60 minutes to produce therapeutic effects and benefits can last up to 90 minutes.[88,89] Patients may take anywhere from 10 to 30 mg per dose, not to exceed five treatments per day. The half-life for the sublingual formulation is about 90 minutes. Nausea and vomiting are common adverse effects for both formulations, and prior to the initiation of apomorphine, patients should be premedicated with the antiemetic, trimethobenzamide. Of note, apomorphine delivered continuously via a subcutaneous infusion for patients with advanced PD and motor fluctuations is currently being studied in clinical trials in the United States. This delivery of apomorphine is currently an approved therapy in Europe.[90]

Pramipexole is initiated at a dose of 0.125 mg three times a day and increased every 5 to 7 days, as tolerated, to a maximum of 1.5 mg three times a day.[91] An extended-release pramipexole formulation is also available. Immediate-release ropinirole is initiated at 0.25 mg three times a day and increased by 0.25 mg three times a day on a weekly basis to a maximum of 24 mg/day.[92] An extended-release ropinirole formulation also is available. Pramipexole is renally excreted with an 8- to 12-hour half-life. The initial dosage must be adjusted in renal insufficiency (0.125 mg twice daily for creatinine clearances of 35-59 mL/min [0.58-0.99 mL/s], 0.125 mg once daily for creatinine clearances of 15-34 mL/min [0.25-0.57 mL/s]).[91]

Ropinirole has a 6-hour half-life and is metabolized by CYP1A2; therefore, potent inhibitors (eg, fluoroquinolone antibiotics) and inducers (eg, cigarette smoking) of this enzyme likely will lead to alterations in its clearance.[92]

Rotigotine transdermal patch is initiated at 2 mg once daily and increased weekly by 2 mg increments to achieve the desired therapeutic effect. The rotigotine transdermal patch provides continuous release of medication over a 24-hour period.[93] The patch application sites should be rotated to minimize skin irritation and rash. Rotigotine disposition is not affected by hepatic or renal impairment, and CYP-mediated interactions are not significant.

EVALUATION OF THERAPEUTIC OUTCOMES

① Comprehensive medication management with optimization of medications related to PD improves patient outcomes.[94–97] Routine evaluation and monitoring of motor and nonmotor symptoms should occur every 3 to 6 months for patients on a stable treatment regimen. With the changes in pharmacotherapy (eg, medication addition, discontinuation, dose change), follow-up monitoring for efficacy and adverse effects should occur within 1 or 2 weeks and may occur via telephone.[98] Table 78-7 lists the monitoring parameters for PD therapy. Patient and caregiver satisfaction is an important component of evaluating therapeutic outcomes. Toward this end, establishing appropriate treatment expectations is important. Patients and caregivers should be educated that symptoms of PD often progresses with time, and adjustments to the medication regimen will be required to manage motor and nonmotor features. Additionally, some symptoms do not respond to pharmacotherapy (eg, freezing, gait, and postural instability). Assessment of the patient's general level of functioning, including activities of daily living and mobility, is important to determine when medication adjustments or physical therapy interventions are needed. It is also important to be aware of and adhere to the general guidelines and recommendations for geriatric health maintenance and disease prevention (eg, bone health, routine vaccinations, and vitamin and mineral supplementations).

TABLE 78-7

Monitoring Parkinson Disease Therapy

1. Monitor medication administration times. Educate the patient that immediate-release carbidopa/L-dopa is absorbed best on an empty stomach but is commonly taken with food (preferably nonprotein snack) to minimize nausea. Avoid administration of conventional selegiline in the late afternoon or evening to minimize insomnia.
2. Monitor to ensure that the patient and/or caregivers understand the prescribed medication regimen. For example, they should understand that catechol-*O*-methyltransferase inhibitors work by enhancing the effect of L-dopa and that the patient should not discontinue medication without notifying the clinician.
3. Monitor and inquire specifically about dose-by-dose effects of medication, including response to doses of medication and the presence of dyskinesias, "wearing-off" effects, dizziness, nausea, orthostasis, or visual hallucinations. Offer suggestions to help alleviate these or encourage the patient to discuss them with the clinician.
4. Monitor caregiver involvement and facilitation for early detection of abnormal behaviors, dyskinesias, falls, hallucinations, impulsivity, memory problems, mood changes, and sleep disorders.
5. Monitor for nonadherence and, if present, inquire for possible reasons (eg, dosing convenience, financial issues, and adverse effects) and offer suggestions.
6. Monitor for presence of medications that can exacerbate idiopathic Parkinson disease motor features (eg, D_2-receptor blockers).
7. Monitor for presence of medications that can exacerbate nonmotor symptoms. Evaluate whether the presence of an anticholinergic agent is causing confusion or cognitive impairment.

Patients and caregivers can participate in treatment by recording medication administration times as well as the duration of "on and off" times that can be reviewed at each visit. Periodic review of all prescription and nonprescription medications that the patient is taking should be performed to identify medication therapy problems such as the use of medications with adverse effects that can exacerbate PD motor and nonmotor features. For example, D_2 blockers (such as metoclopramide and firstgeneration antipsychotics) can worsen motor features and should be avoided. If the patient reports memory problems, medications with anticholinergic properties should be avoided.

Nonmotor symptoms must be identified, assessed, managed, and monitored. These include anxiety, cognitive impairment, constipation, daytime sleepiness, depression, drooling, dysphagia, fatigue, falls, hallucinations/psychosis, impulsivity, insomnia, orthostatic hypotension, overactive bladder, pain, REM sleep behavior disorder, and restless legs syndrome. Screening for anxiety or depressive disorders will help determine if antidepressant or antianxiety therapy is needed.[99] If falling is a problem, it is important to investigate whether falls are secondary to insufficient motor control, orthostatic hypotension, or medication adverse effects, such as dizziness. The former may necessitate an increase in dose of antiparkinsonian agents, and the latter two conditions, a reduction in medication dosage. Physical therapy is also helpful for strengthening ambulation and balance skills to minimize falls. The patient should be questioned about any difficulties with their antiparkinsonian medications, including presence of adverse effects. Recommendations always should be made in view of the patient's perception of the severity of symptoms and effect on quality of life.

CONCLUSION

Despite many advances in neuroscience, a definitive cause of PD remains unknown. Each of the available therapies provide various degrees of symptomatic benefit, and the choice of agent is patient specific. The appropriate pharmacotherapy can significantly improve a patient's quality of life and functional status. The goal of management remains maintaining acceptable functional control with minimal treatment emergent motor and nonmotor complications. Thoughtful consideration for choice of initial and adjunctive therapy is critical for optimizing short- and long-term outcomes.

ABBREVIATIONS

COMT	catechol-*O*-methyltransferase
CR	controlled release
CYP450	cytochrome P450
D_1	dopamine receptor subtype 1
D_2	dopamine receptor subtype 2
DBS	deep-brain stimulation
ER	extended release
GABA	γ-aminobutyric acid
GI	gastrointestinal
GPi	globus pallidus interna
IR	immediate release
L-dopa	levodopa
MAO	monoamine oxidase
NMDA	*N*-methyl-D-aspartate
ODT	orally disintegrating tablet
PD	Parkinson disease
REM	rapid eye movement
SNc	substantia nigra pars compacta
SNr	substantia nigra pars reticulate

SELF-ASSESSMENT QUESTIONS

1. Parkinson disease (PD) is characterized by a nigrostriatal deficiency of

    A. Acetylcholine.

    B. Dopamine.

    C. Norepinephrine.

    D. Serotonin.

2. The clinical diagnosis of PD is based on the presence of bradykinesia and at least one of three other features: muscular rigidity, resting tremor, and/or

    A. Dystonia.

    B. Nystagmus.

    C. Postural instability.

    D. Seizures.

3. Which of the following is the most effective drug for PD?

    A. Amantadine

    B. Carbidopa/levodopa

   C. Pramipexole

   D. Rasagiline

4. An 80-year-old with newly diagnosed PD and a history of memory problems and confusion is best treated with

   A. Amantadine.

   B. Carbidopa/levodopa.

   C. Trihexyphenidyl.

   D. Ropinirole

5. The mechanism of action for entacapone is

   A. COMT inhibition.

   B. MAO-B inhibition.

   C. D_2-receptor inhibition.

   D. Dopa-decarboxylase inhibition.

6. Which of the following agents can worsen PD symptoms?

   A. Haloperidol

   B. Ondansetron

   C. Pimavanserin

   D. Rasagiline

7. A patient with PD is taking carbidopa/levodopa 25/100 mg three times a day and reports that they tend to slow down 2 hours before his next carbidopa/levodopa dose. This patient is most likely experiencing

   A. Delayed-onset response

   B. Dyskinesia

   C. Freezing

   D. "Wearing off"

8. A 70-year-old patient taking carbidopa/levodopa 25/100 mg three times a day for PD is experiencing end-of-dose "wearing off." Carbidopa/levodopa is the only medication they take for PD and adherence is excellent. The best next step is to

   A. Add tolcapone.

   B. Consider surgery.

   C. Add trihexyphenidyl.

   D. Increase carbidopa/levodopa to four times daily.

9. A 63-year-old patient taking carbidopa/levodopa 25/100 mg four times a day for PD is experiencing end-of-dose "wearing off." The patient would

like a medication that is only dosed once a day that may reduce this effect. The best recommendation is to

A. Add tolcapone.

B. Add entacapone.

C. Add opicapone.

D. Add inhaled levodopa.

10. A 72-year-old patient with moderate-to-severe PD was placed on carbidopa/levodopa 25/100 mg three times a day by his primary care physician. They are complaining of nausea and stomach upset since starting the medication. The best recommendation is to

A. Increase the carbidopa/levodopa dose by 50%.

B. Discontinue the medication and switch to rasagiline.

C. Discontinue the medication and switch to a ropinirole.

D. Recommend taking carbidopa/levodopa with a nonprotein snack.

11. A 71-year-old patient has had PD for 8 years and is currently taking pramipexole 1.5 mg three times a day and carbidopa/levodopa 25/100 mg four times a day. Their spouse claims that they are complaining of seeing spiders and bugs running across the floor and imaginary children in their house. The patient is diagnosed with PD psychosis. At this point, the best recommendation is to

A. Increase the pramipexole dose.

B. Reduce the pramipexole dose.

C. Increase the carbidopa/levodopa dose.

D. Reduce the carbidopa/levodopa dose.

12. A 65-year-old patient with PD is experiencing moderate dyskinesias that are bothersome. The patient is on carbidopa/levodopa 25/100 mg two tablets at 7 am and one tablet at 11 am, 2 pm, 5 pm, 8 pm, and 11 pm. Which of the following is most appropriate?

A. Add amantadine

B. Add entacapone

C. Add rasagiline

D. Add apomorphine

13. A 63-year-old patient with PD has done well on rasagiline 1 mg once a day and ropinirole 4 mg three times a day for several years. In the past, higher doses of ropinirole resulted in excessive drowsiness. They are not experiencing "wearing off" fluctuations or dyskinesias. Physical examination reveals clinically significant slowness and rigidity and the patient desires more symptom relief. At this point, the best recommendation would be to

A. Add carbidopa/levodopa.

B. Add entacapone.

C. Add pramipexole.

D. Consider DBS surgery.

14. You are educating a patient with PD on their new prescription for apomorphine. Which of the following should the patient be informed of as

common adverse effects?

A. High blood pressure

B. Dry mouth

C. Nausea

D. Livedo reticularis

15. A 74-year-old patient has had PD for 8 years and is currently taking carbidopa/levodopa 25/100 mg one and a half tablets five times a day. They are experiencing troublesome hallucinations. Previous attempts to lower the carbidopa/levodopa dose were not tolerated due to significant worsening of motor symptoms. The best recommendation is to add

A. Risperidone.

B. Haloperidol.

C. Pimavanserin.

D. Ropinirole.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** See Figs. 78-1 and 78-2. At the cellular level, degeneration of dopaminergic neurons resulting in a deficiency of dopamine within the nigrostriatal system is a hallmark of PD. In PD, deficiencies of acetylcholine, norepinephrine, and serotonin may occur in other parts of the brain.

2. **C.** See Table 78-1. The clinical diagnosis of PD requires the presence of bradykinesia and at least one of the following: resting tremor, rigidity, and/or postural instability. The concurrent presence of dystonia, nystagmus, or seizures would suggest an atypical form of parkinsonism.

3. **B.** Levodopa is the immediate precursor of dopamine and, in combination with a peripherally acting L-amino acid decarboxylase inhibitor (carbidopa or benserazide), remains the most effective drug for the symptomatic treatment of PD. Regardless of what the initial therapeutic agent is (eg, amantadine, dopamine agonist, or rasagiline) ultimately, all patients with PD will require levodopa.

4. **B.** See Table 78-4. Anticholinergic medications (eg, trihexyphenidyl) should be used with caution in older patients and in those with pre-existing cognitive difficulties due to anticholinergic adverse effects exacerbating confusion. Amantadine should be avoided as adverse effects include confusion and hallucinations with older patients being particularly prone to developing confusion. Dopamine agonists (eg, ropinirole) should also be avoided in the older patients especially those with preexisiting cognitive difficulties.

5. **A.** Entacapone is an inhibitor of catechol-*O*-methyltransferase (COMT). Examples of monoamine oxidase type-B (MAO-B) inhibitors are rasagiline, safinamide, and selegiline. An example of a dopa-decarboxylase inhibitor is carbidopa. Examples of medications that inhibit D_2 receptors include metoclopramide, prochlorperazine, and first-generation antipsychotics such as haloperidol.

6. **A.** Haloperidol blocks D_2 receptors and will worsen the motor symptoms of PD and is associated with medication-induced parkinsonism (see Table 78-1). Ondansetron is an antiemetic that works as a $5HT_3$ antagonist and is not implicated in worsening PD symptoms like the D_2 receptor blockers prochlorperazine and metoclopramide. Pimavanserin does not block D_2 receptors nor does rasagiline and both are FDA-indicated for the treatment of PD (pimavanserin for PD psychosis and rasagline for symptoms of PD) (Table 78-1).

7. **D.** End-of-dose "wearing off" is a common type of response fluctuation and is reported as the onset of “off” periods (or slowing down in movements) prior to the next dose of medication. “Delayed-on” or “no-on” responses describe a delayed or absent onset of drug effect to individual doses of carbidopa/levodopa. “Freezing” is a sudden, episodic akinesia of the lower extremities and described by patients as a feeling where their “feet suddenly feel stuck to the floor” during ambulation or they have difficulty initiating steps (start hesitation) or turns (turn hesitation). Freezing often is exacerbated by anxiety or when perceived obstacles (eg, doorways, turnstiles) are encountered. Dyskinesias are involuntary choreiform

movements involving usually the neck, trunk, and lower/upper extremities and usually associated with peak striatal dopamine levels (peak-dose dyskinesia) and, simplistically, can be thought of as too much movement secondary to extension of the levodopa pharmacologic effect. See "Carbidopa/L-Dopa" section.

8. **D.** With advancing PD, the duration of action of a single carbidopa/levodopa progressively shortens. As a result, carbidopa/levodopa needs to be given more frequently. Given that this patient has excellent adherence to carbidopa/levodopa, increasing the carbidopa/levodopa frequency to four times per day is the next best step prior to the addition of additional medications for "wearing-off" or consideration for surgery.

9. **C.** With advancing PD, the duration of action of a single carbidopa/levodopa progressively shortens. As a result, carbidopa/levodopa needs to be given more frequently or the addition of adjunctive medications for "wearing-off" must be considered. Opicapone is an inhibitor of catechol-*O*-methyltransferase (COMT) that is administered once daily to reduce motor fluctuations. Both tolcapone and entacapone are also COMT inhibitors, but require administration with each dose of carbidopa/levodopa. Inhaled levodopa may provide relief for "wearing off," but would likely require administration every time "wearing off" occurs, which in this case is four times a day.

10. **D.** See Tables 78-4 and 78-7. Nausea is a common adverse effect of carbidopa/levodopa and administration with food (preferably a nonprotein snack) is the first step in minimizing nausea. Increasing the carbidopa/levodopa dose by 50% will exacerbate the nausea and discontinuation of the carbidopa/levodopa is not appropriate at this stage.

11. **B.** See Table 78-2. Hallucinations and delusion should be managed using a systematic approach that starts with dose reduction or discontinuation of the dopamine agonist. Increasing the dose of antiparkinson medication will worsen the patient's symptoms of psychosis.

12. **A.** See Table 78-4. Amantadine is often used for management of levodopa-induced dyskinesia. The antidyskinetic properties of amantadine are presumed to be mediated by antiglutamate properties that, in the setting of dyskinesias, dominate over dopaminergic properties. The addition of entacapone, rasagiline, or apomorphine will likely worsen pre-existing dyskinesias.

13. **A.** Levodopa remains the most effective symptomatic medication and, regardless of what the initial therapeutic agents are; ultimately, all patients with PD will require levodopa. For this patient, the addition of carbidopa/levodopa would be the best recommendation. Addition of entacapone would be ineffective as the patient is not currently on carbidopa/levodopa. The addition of pramipexole (a dopamine agonist) is inappropriate because the patient is currently on ropinirole, which is also a dopamine agonist. Surgery is reserved for patients with fluctuations or dyskinesia that are not responding to other therapies. See "Pharmacologic Therapy" section.

14. **C.** See Table 78-4. Nausea is a common side effect of dopamine agonists. Apomorphonine requires close initial titration due to the risk of orthostatic hypotension, not high blood pressure. Dry mouth is an anticholinergic adverse effect of benztropine or trihexyphenidyl. Livedo reticularis is an adverse effect of amantadine.

15. **C.** See Table 78-2. Pimavanserin is FDA-approved for management of psychosis in PD. Risperidone and haloperidol are potent inhibitors of D_2 receptors and should be avoided due to risk of worsening motor symptoms of parkinsonism. Ropinirole is a dopamine agonist and will worsen pre-existing hallucinations/psychosis in patients with PD.

Chapter 79: Pain Management

Chris M. Herndon; Courtney M. Kominek; Amanda M. Mullins

KEY CONCEPTS

KEY CONCEPTS

① Understanding the pathogenesis of pain should guide treatment and patient education.

② Whenever possible ask patients if they have pain to identify the source of pain and to assess the characteristics of the pain.

③ The etiology of pain may not always be identifiable.

④ A multidisciplinary approach that includes incorporation of nonpharmacologic strategies for pain management should be undertaken.

⑤ Chronic pain treatment should focus on self-management strategies and focus on active rather than passive approaches.

⑥ Selection of nonopioids and opioids should be based on the characteristics and type of pain as well as individual patient factors.

⑦ Oral or topical analgesics are preferred over other dosage forms whenever feasible, but it is important to adjust the route of administration based on the patient's needs.

⑧ Patients taking analgesics should be monitored for response (analgesia, functionality, quality-of-life) and medication adverse effects.

⑨ Doses must be individualized for each patient and administered for an adequate duration of time. Around-the-clock regimens should be considered for acute and chronic pain. As-needed regimens should be used for breakthrough pain or when acute pain displays wide variability and/or has subsided greatly.

⑩ Consider a trial of opioids in those with severe pain who have failed nonpharmacologic and nonopioid treatment only when the anticipated benefits are expected to outweigh the risks.

⑪ Use risk mitigation strategies such as informed consent/patient agreements, urine toxicology monitoring, opioid overdose education and naloxone distribution (OEND), and prescription drug monitoring programs (PDMP) checks when necessary.

INTRODUCTION

> *If we know that pain and suffering can be alleviated, and do nothing about it, then we ourselves, become the tormentors.*
>
> —Primo Levi[1]

Humans have always known and sought relief from pain.[2] Today, pain's impact on society is still great, and pain remains a primary reason why patients seek medical advice.[3] In general, pain is defined as: "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[4] However, as pain is subjective, many clinicians define pain as "whatever the patient says it is."

Regrettably, many healthcare providers do not receive adequate training in pain management. Therefore, understanding its pathophysiology and maintaining a thorough understanding of both nonpharmacologic and pharmacologic treatment modalities are important factors in addressing pain control.

EPIDEMIOLOGY

Data collected by the National Health Interview Survey suggest that greater than 50 million persons in the United States live with chronic pain.[5] Of whom, 7.5% report "high impact pain," which is considered chronic pain that limits life or work activities on most days or every day.[5] In 1 year, an estimated 25 million Americans will experience acute pain due to injury or surgery, and one-third will experience severe chronic pain at some point in their lives.[3] Unfortunately, despite much public attention, pain often remains inadequately or inappropriately treated.[6,7]

PATHOPHYSIOLOGY

① Pain pathophysiology involves complex interactions between neural and immune networks within the peripheral and central nervous system (CNS) in response to afferent sensory stimuli that produce the conscious experience we know as pain. It can be physiologic and protective (adaptive) or pathophysiologic and harmful (maladaptive).[8] Pain is a complex interaction between biological processes (nociception) impacted by individual psychological and social determinates.

Adaptive Pain

The pain experienced from noxious stimuli involving temperature extremes, mechanical trauma, or chemical irritation is called nociceptive pain which is a primitive evolutionary mechanism to protect our body from actual or potential tissue injury. Pain that occurs as a result of unavoidable tissue damage (trauma or surgery) creates sensitization at and adjacent to the site of tissue injury. This process also engages the immune system and is called inflammatory pain. Nociceptive and inflammatory pains are both adaptive and protective. The physiological processing of pain occurs within a neurotransmission circuit via a number of steps known as transduction, conduction, transmission, modulation, and perception.[8]

Transduction

The first step leading to the sensation of pain is stimulation of specialized nerve fiber receptors known as *nociceptors*. These high-threshold receptors are found in both somatic and visceral structures and help to discriminate between noxious and innocuous stimuli. Nociceptors are activated and subsequently sensitized by mechanical, thermal, and chemical stimuli.[8] The underlying mechanism of these noxious stimuli, which in and of themselves may sensitize/stimulate the receptor, may be the release/activation of numerous cytokines and chemokines that sensitize and/or activate the nociceptors (Fig. 79-1).[8–10]

FIGURE 79-1

Conduction

Nociceptor activation leads to the conversion of a chemical signal into an electrical signal through voltage-gated sodium channels, which produce the generation of action potentials that are conducted along primary afferent A-δ and C-polymodal nerve fibers to the dorsal horn of the spinal cord.[11,12] Stimulation of large-diameter, sparsely myelinated A-δ fibers evokes sharp, well-localized pain, whereas stimulation of unmyelinated, small-diameter C fibers produces aching, poorly localized pain.[13]

Transmission

These afferent, nociceptive pain fibers synapse in various layers (laminae) of the spinal cord's dorsal horn and convert the electrical signal back into a chemical signal by releasing excitatory neurotransmitters, such as glutamate and substance P. The N-type voltage-gated calcium channels regulate the release of these excitatory neurotransmitters. The complex array of events that influence pain can be explained in part by the interactions between neuroreceptors and neurotransmitters that take place in this synapse. Pain signals reach the brain through a host of ascending spinal cord pathways, which include the neo- and paleospinothalamic tract.[13] Other sensory information is also carried along these pathways. Thus, pain is influenced by many factors supplemental to nociception, which prevents simple schematic representation. The thalamus acts as a relay station within the brain, as these pathways ascend and pass the impulses to higher cortical structures where pain can be processed further.[13]

Modulation

The brain and spinal cord modulate pain through a number of intricate processes, and transmission may be facilitated by neurotransmitters such as glutamate or substance P to make the signals stronger and the pain more intense. Alternatively, the signal can be attenuated/inhibited by descending pathways that consist of endogenous opioids (eg, enkephalins and β-endorphins), γ-aminobutyric acid (GABA), norepinephrine, or serotonin.[14–16] Like exogenous opioids, endogenous peptides bind to opioid receptor sites and modulate the transmission of pain impulses.[14] Other receptor types, such as the glutamate receptor, also can influence this system. Blockade of one such receptor, *N*-methyl-D-aspartate (NMDA), may increase the mu (μ)-receptors' responsiveness to opiates.[17]

Perception

The complex interplay between ascending excitatory and descending inhibitory pathways is thought to culminate in a conscious experience that takes place in higher cortical structures. While not well understood, cognitive and behavioral functions can modify pain; thus, relaxation, distraction, meditation, and guided mental imagery may strongly influence pain perception and decrease pain.[18,19] In contrast, conditions such as depression or anxiety often worsen pain.[20]

Impact of Immune System on Pain Signaling

Over the past two decades, a two-way communication exists between neurons and immune cells within the CNS, especially astrocytes and microglia which are the equivalent of a macrophage within the CNS.[17,21] Their activation within the CNS in response to peripheral and central nerve injury leads to a complex cascade of events responsible for the ongoing pain seen in neuropathic pain conditions. Activated microglia may also play a role in the development of opioid tolerance and opioid-induced hyperalgesia. Evidence is emerging that the interface between immune cells and neurons in the CNS plays a significant role in the maintenance of chronic pain and may offer attractive new potential therapeutic targets.[22]

Maladaptive (Pathologic) Pain

① Pathophysiologic pain is distinctly different from nociceptive pain, in that it becomes disengaged from noxious stimuli or healing and often is described in terms of chronic pain. This type of pain is a result of damage or abnormal functioning of the peripheral nervous system (PNS) and/or CNS.[17] Maladaptive pain can be neuropathic, in which there is ongoing peripheral nerve injury (eg, postherpetic neuralgia, painful diabetic neuropathy, or chemotherapy-induced neuropathy), or in the CNS (eg, following an ischemic stroke or with multiple sclerosis). Maladaptive pain may also be centralized, where no nerve injury or inflammation exists, but a centrally mediated disturbance in pain processing within the CNS leads to pain hypersensitivity and subsequently spontaneous pain. Classic examples are fibromyalgia, irritable bowel syndrome, temporomandibular joint disorder, and myofascial pain syndrome. Chronic pain states are often mixed with all three mechanisms (nociceptive, neuropathic, and centralized) simultaneously.[23] These pain syndromes are frequently challenging to diagnose and difficult to treat. In addition, the pain reported is often not commensurate with physical exam findings or imaging results, which may result in undertreatment and ultimately inadequate pain relief.

The mechanism responsible for pain of this nature may be the nervous system's dynamic nature. Nerve damage or certain disease states may cause both peripheral (eg, alteration in nociceptive nerve fiber sensitivity, alteration of sodium channels, collateral sprouting of nerve fibers) and central (eg, hyperexcitability of central neurons or central sensitization, NMDA-glutamate receptor activation, central disinhibition) changes in neurotransmission leading to increased pain.[14,17] Pain circuits may rewire themselves both anatomically and biochemically (often referred to as neural plasticity), and this produces a mismatch between pain stimulation and inhibition, potentially resulting in a progressive increase in the discharge of dorsal horn neurons.[24] The end result is chronic pain, where patients may present with episodic or continuous pain transmission (often described as burning, tingling, shock-like, or shooting), exaggerated painful response to normally noxious stimuli (hyperalgesia), and/or painful response to normally non-noxious stimuli (allodynia).[13,25,26] This change over time may help explain why this type of pain often manifests long after the injury or when no actual injury is identified.

CLASSIFICATION OF PAIN

①②③It is helpful in guiding the assessment and treatment of pain to classify or subdivide the presenting symptoms by the type of pain (eg, nociceptive, neuropathic, inflammatory), by pain intensity (eg, mild, moderate, or severe), or most commonly by duration of pain (eg, acute, subacute, or chronic pain).

Acute Pain

②③Acute pain is a beneficial physiologic process, serving its adaptive purpose by warning individuals of disease states and potentially harmful situations. Unfortunately, severe, unremitting, under-treated acute pain, when it outlives its biologic usefulness, can produce many deleterious effects. Aside from unnecessary suffering, poorly treated acute pain also increases one's risk for the development of chronic pain syndromes.[27] Acute pain is typically short in duration, lasting less than 30 days and is often due to an identifiable cause and is usually nociceptive in nature with common causes including surgery, acute illness, trauma, labor, medical procedures, and cancer or cancer treatment.[28]

Chronic Pain

⑤Under normal conditions, acute pain subsides quickly as the healing process decreases the pain-producing stimuli; however, in some instances, pain persists for months to years, leading to a chronic pathologic pain state with features quite different from those of acute pain (Table 79-1).[28,29] In many cases, the exact etiology of pain may not be identifiable; therefore, chronic pain can be classified as either being associated with cancer (cancer pain) or from noncancer etiologies (chronic noncancer pain). Chronic noncancer pain is often a result of changes to nerve function and transmission, thus making treatment more challenging.[30]

TABLE 79-1

Characteristics of Acute and Chronic Pain

Characteristics	Acute Pain	Chronic Pain
Relief of pain	Highly desirable	Highly desirable
Dependence and tolerance to medication	Unusual	Common
Psychological component	Usually not present	Often a major problem
Organic cause	Common	May not be present
Environmental/family issues	Small	Significant
Insomnia	Unusual	Common component
Treatment goal	Cure	Functionality
Depression	Uncommon	Common

Data from References [28] and [29].

Cancer Pain

①②④Pain associated with potentially life-threatening conditions is often called malignant pain or cancer pain.[32] This type of pain includes both chronic and acute (eg, breakthrough pain) components and often has multiple etiologies. This pain may be caused by the disease itself (eg, tumor invasion, organ obstruction), associated with treatment (eg, anticancer, radiation, and surgical incisions), or as a result of diagnostic procedures (eg, biopsy).[32] Breakthrough cancer pain may be *idiopathic* (no known precipitating factors)*, incident* (due to a predictable cause), or *end of dose failure* (predictable worsening of pain at the end of an analgesic's pharmacodynamic efficacy).[33] Regardless of duration of pain, or suspected underlying etiology, a standardized approach to evaluation of a pain complaint is imperative. Cancer pain crises, frequently considered an acute pain overlaying an ongoing chronic pain, should be considered a medical emergency. Additional information about cancer pain can be found in Chapter 150, "Supportive Care."

CLINICAL PRESENTATION

②④A patient-oriented approach is essential, and symptom assessment methods for pain should not differ from those used in other conditions.[34] Therefore, a comprehensive history and physical examination is imperative to evaluate underlying diseases and possible other contributing factors.[28] This includes asking if the patient has pain and identifying the source of pain when possible; however, the absence of a discreet etiology should not preclude appropriate treatment.[28] A baseline characterization of pain should be obtained using a symptom assessment mnemonic (eg, OLDCARTS, SOCRATES, SCHOLAR-MAC, or PQRST).[31] Ongoing assessment should occur using a consistent and validated method (ie, Wong Baker Faces Scale, Brief Pain Inventory, Numeric Rating Scale, or Pain-Enjoyment-General Activity Scale).[35]

CLINICAL PRESENTATION: Acute and Chronic Pain

Acute Pain

General

- Look for obvious distress (eg, trauma). In infants, presentation may include changes in feeding habits, increased fussiness, or being inconsolable. Those with dementia may exhibit changes in eating habits, increased agitation, or calling out. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear are noted to lower this threshold, whereas rest, mood elevation, sympathy, distraction, and understanding raise the pain threshold symptoms.

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these occur in a timely relationship with an obvious noxious stimuli).

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor, but these signs are *not diagnostic.*
- In some cases, there are no obvious physical signs.
- Comorbid conditions usually not present.
- Outcome of treatment generally predictable.

Laboratory Tests

- Pain is always subjective.
- There are no specific laboratory tests for pain.
- Pain is best diagnosed based on patient description and history.

Chronic Pain

General

- Can appear to have no noticeable suffering. Attention also must be given to mental/emotional factors that alter the pain threshold, similar to acute pain.

Symptoms

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these often occur *without* a temporal relationship with an obvious noxious stimuli).
- Over time, the pain stimulus may cause symptoms that completely change (eg, sharp to dull, obvious to vague).

Signs

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor are seldom present.
- In most cases, there are *no* obvious signs.
- Comorbid conditions are often present (eg, insomnia, depression, and anxiety).
- Outcome of treatment is often unpredictable.

Laboratory Tests

- Pain is always subjective.
- Pain is best diagnosed based on patient description and history.
- There are *no* specific laboratory tests for pain; however, history and/or diagnostic proof of past trauma (eg, computed tomography) may be helpful in diagnosing etiology. General labs that may be considered include vitamin D, thyroid stimulating hormone (generalized or widespread

pain), and B12 (neuropathic pain).

Data from Reference [28].

TREATMENT

Achieving desired pain management outcomes includes both nonpharmacologic and pharmacologic strategies.

Desired Outcomes

④⑤The primary goal of pain treatment depends on the type of pain present and should be tailored to individual patients and circumstances (see "Patient Care Process" section). For example, a desired outcome in the acute postoperative setting may be to achieve a level of pain relief that allows the patient to attain certain functional goals, such as deep breathing or participation in physical therapy. In comparison, the goals in chronic noncancer pain may be to improve or maintain the patient's level of functioning, decrease pain perception, reduce medication use when possible, improve the patient's quality of life, and minimize the adverse effects of analgesics. [33]

Nonpharmacologic Therapy

②③⑤The use of nonpharmacologic therapies should always be considered first-line therapy, either alone or in combination with appropriate analgesics. It is important to target all aspects of the biopsychosocial model when treating pain. Collaborating with other professions who are trained to provide nonpharmacologic approaches is essential. In addition, focusing on active therapies over passive therapies is encouraged. The evidence basis for many of the nonpharmacologic approaches is in evolution, and the results of these approaches can have varied efficacy based on the skill of the individual applying the modality as well as the type of pain being treated.

A variety of nonpharmacologic approaches are available. These include physical therapy, manipulation, formal exercise programs, weight loss, and diet changes (Table 79-2).[36–39] There are numerous complementary and integrative approaches with evidence in pain treatment that include acupuncture, Tai chi, yoga, mindfulness, meditation, relaxation, and biofeedback.[40,41] Complementary and integrative approaches to the treatment of chronic pain are outlined in Table 79-3.[40]

TABLE 79-2

Nonpharmacologic Approaches to the Treatment of Pain

- Exercise
- Physical therapy
- Diet
    - Anti-inflammatory
    - Elimination
- Weight loss
- Electroanalgesia: application of electrical stimulation to various areas that range from noninvasive to highly invasive
    - Noninvasive: transcutaneous electrical nerve stimulation (TENS)
    - Minimally invasive: percutaneous electrical nerve stimulation (PENS)
    - Highly invasive: spinal cord stimulation (SCS)
- Interventional approaches

- Cognitive behavioral therapy for chronic pain
- Multidisciplinary rehabilitation programs

Data from References [38, 41,42].

TABLE 79-3

Complementary and Integrative Approaches for Chronic Pain

Intervention	Description	Evidence	Safety
Tai Chi	• Low-impact • Mind body exercise • Started in China as a martial art • Slow mindful movement with attention to breathing and relaxation	• Osteoarthritis • Chronic low back pain (CLBP) • Fibromyalgia	Minor musculoskeletal aches and pains
Yoga	• From India • Blend of meditation, breathing, and physical postures	• Osteoarthritis • Rheumatoid Arthritis • Kyphosis • Fibromyalgia • Low back pain (LBP) • Neck pain	• Similar to musculoskeletal pain associated with physical therapy (PT) • Discuss with provider/yoga instructor if glaucoma or osteoporosis
Acupuncture	• Stimulation of certain points of the body typically with the insertion of needles into the skin • East Asian	*Acute:* • Post-surgical pain (reduces opioid dose) • Migraine • Acute/subacute LBP • Ankle sprain *Chronic:* • CLBP • Osteoarthritis (knee, hip, general) • Temporomandibular disorder (TMD) • Headache • Migraine • Neck pain • Shoulder pain • Peripheral neuropathy (diabetic, HIV, Bell's palsy, Carpal Tunnel Syndrome [CTS]) Fibromyalgia	• Low risk for adverse effects • Minor: itching, relaxation, tired • Rare: pneumothorax, infections (associated with poor training)
Massage	Soft tissue manipulation	*Acute:*	Low risk for adverse

		• Postoperative pain *Chronic:* • CLBP • Neck and shoulder pain • Osteoarthritis • Heel pain • Epicondylitis Fibromyalgia	effects
Mindfulness, meditation, and relaxation	• A variety of mind-body practices to capitalize on body's own calming response through reducing blood pressure and slower breathing. • Examples: mindfulness-based stress reduction (MBSR), cognitive behavioral therapy (CBT), pain-coping skills training (PCST), diaphragmatic breathing, progressive muscle relaxation, hypnosis, acceptance and commitment therapy, music therapy, guided imagery	*Acute:* • Burn patients (music therapy) • Acute/procedural pain (music therapy, hypnosis, guided imagery) *Chronic:* • LBP (MBSR, CBT, • Chronic pain (music therapy, CBT, guided imagery, ACT, progressive relaxation) • Headache (mindfulness and relaxation, MBSR) • Fibromyalgia (relaxation, guided imagery) • Knee pain (PCST) • Osteoarthritis (PCST, guided imagery) • Rheumatoid arthritis (PCST, guided imagery) • Diabetic neuropathy (mindfulness/meditation) • TMD (relaxation)	Rare adverse reactions (psychiatric patients, epilepsy, hx of trauma)
Biofeedback	Mind-body practice in which patients are connected to a device that measures their bodily functions (BP, HR, RR) and use the information to alter thoughts and behaviors	• Tension/migraine headache • CLBP • Fibromyalgia • Shoulder pain	No to low risk of adverse reactions
Manipulation	Treatment of spine and other joints	• Osteoarthritis (hip, knee, ankle, plantar fasciitis, ankle, shoulder, epicondylitis) • LBP • CTS	• Musculoskeletal aches and pains • Uncommon serious adverse reactions (cervical artery

		• TMD	dissection, stroke, neck injury)

Data from References 38, 40,48–51.

⑤Simple interventions (eg, education or introductory information about expected discomfort or pain after certain procedures) reduce patient distress and help reduce post-procedure pain.[43] Psychological techniques (eg, cognitive-behavioral therapy, relaxation training, mindfulness-based stress reduction) are effective in reducing pain-related disability and improving global functioning in patients with numerous types of chronic pain.[40,44] Multidisciplinary rehabilitation programs with both psychological and physical components improve pain, function, and disability.[39,42]

Electroanalgesia involves the application of electrical stimulation to various locations and range from noninvasive (eg, transcutaneous or percutaneous electrical nerve stimulation) to highly invasive (implanted spinal cord stimulation).[39,45] Transcutaneous electrical nerve stimulation (TENS) may reduce pain by enhancing natural descending inhibitory pathways within the CNS. The frequency of the electrical stimulation delivered, presence or absence of systemic analgesics, and the type of underlying pain may affect the overall efficacy of this treatment.[46] Although data are conflicting on the efficacy of TENS, with its low risk for adverse effects, it remains a practical option.[45,47]

Pharmacologic Therapy

Appropriate Patient Selection

⑥⑦⑧⑨Pharmacologic treatment is often considered the cornerstone of pain management. The potential for benefit with each pharmacologic option, as well as the risk of adverse effects, must be assessed at baseline and periodically when determining the optimal therapeutic plan for an individual patient. The potential for benefit with each pharmacologic option, as well as the risk of adverse effects, must be assessed at baseline and periodically.

Patient Selection Considerations in Acute or Cancer Pain

⑨⑩⑪The World Health Organization (WHO) recommends a three-step ladder approach using the nonopioids as initial treatment and escalating treatment to either “weak” or “strong” opioids based on pain intensity ratings (ie, mild, moderate, or severe).[52] Patient-specific factors, for example, renal or liver dysfunction that would potentially limit treatment with many nonopioid therapies, may lead clinicians to initiate therapy with an opioid to optimize pain relief while minimizing adverse effects. Acute cancer pain crises should be considered a medical emergency and specifics regarding its treatment are included in Chapter 150, “Supportive Care.” Inadequate analgesia, opioid-related adverse effects, or loss of an administration route may require rotation to another opioid analgesic. The process for equianalgesic opioid rotation is provided in Table 79-4.[53]

TABLE 79-4

Steps for Equianalgesic Opioid Calculation

Step 1. Use the equianalgesic dose chart in Table 79-5 for a first estimate of the dose of the new medication that is equianalgesic to the old medication.

Step 2. Record the total dose of each opioid given during the past 24 hours. If both parenteral and oral doses of the same opioid were given, calculate a separate total for each.

Step 3. Divide each 24-hour total by the equianalgesic dose in Table 79-5 for that opioid and route, converting the dose into equianalgesic dose units. Add the equianalgesic dose units for all medications and routes (ie, some clinicians prefer to convert all opioid doses to "oral morphine equivalents" prior to calculating new target dose).

Step 4. Estimate the dose of the new medication by multiplying the sum obtained in Step 3 by the equianalgesic dose for the new medication and route (see example below*).

Step 5. Modify the initial estimate based on the clinical situation and the specific medications involved. Factors that enter into this process include the following:

a. Effective analgesia, intolerable adverse effects: calculate the dose of the new opioid as outlined in Steps 1 to 4. Reduce target dose by 25% to 50% to account for lack of cross-tolerance between various opioids.

b. Ineffective analgesia, no intolerable adverse effects: calculate the dose of the new opioid as outlined in Steps 1 to 4. Reduction in target dose outlined in (a) may be disregarded depending on clinical situation and patient-specific variables. Those with severe pain on regularly scheduled opioids for >5 days may have their dose increased by 30% to 50% or an increase equal to the use of supplemental PRN medication per day averaged over the previous 2 to 3 days. Consider more conservative increases (ie, 10%-20%) in the first few days of therapy in those who have less severe pain or who are frail. Dose increases are safest after steady-state has been approached (typically 5-6 half-lives).

Step 6. Should PRN dosing of an immediate release medication be necessary for break-through pain, provide 10% to 15% of total daily dose of new opioid every 3 to 4 hours depending on individual opioid's duration of analgesia.

Step 7. Reassess the patient frequently following opioid rotation (48-72 hours following dose change).

Data from Reference [53].

TABLE 79-5

Opioid Analgesics

Class and Generic Name (Brand Name)	Chemical Source	Metabolic Pathway/Metabolites	Route[a]	Equianalgesic Dose in Adults (mg)	Approximate Onset (min)/Half-Life (h)[b]
Phenanthrenes (morphine-like agonists)					
Morphine (numerous)	Naturally occurring	Phase II via glucuronidation/M3G[c] (inactive) and M6G[d] (active)	IM/IV	10	10-20/2
			PO	25	30-40/2
Hydromorphone (Dilaudid, Exalgo, various)	Semisynthetic	Phase II via glucuronidation/H3G (active)[e], H6G[f]	IM/IV	1.5	10-20/2-3
			PO	7.5	

Oxymorphone (Numorphan, Opana)	Semisynthetic	Phase II via glucuronidation/O3G (inactive)[g]	IM/IV	1	10-20/2-3
			PO	10	
Levorphanol (various)	Semisynthetic	Phase II via glucuronidation/levorphanol-3-glucuronide (inactive)	PO	Variable	10-20/12-16
Codeine (various)	Naturally occurring	CYP2D6/morphine (active), Phase II glucuronidation/codeine-6-glucuronide (unknown), CYP3A4/norcodeine (inactive)	PO	15-30[h]	10-30/3
Hydrocodone (available as combination, single entity extended release—Hysingla ER[i], Zohydro ER)	Semisynthetic	CYP3A4/norhydrocodone (inactive); CYP2D6/hydromorphone (active)	PO	5-10[h]	30-60/4
Oxycodone (OxyContin, Xtampza)[i]	Semisynthetic	CYP3A4/noroxycodone (active), CYP2D6/oxymorphone (active)	PO	15-30[j]	30-60/2-3
Phenylpiperidines (meperidine-like agonists)					
Meperidine (Demerol, various)	Synthetic	Phase II hydrolysis/meperidinic acid, CYP2B6, CYP3A4, & CYP2C19/normeperidine	IM/IV	75	10-20/3-5
			PO	300[j]; not recommended	
Fentanyl (Sublimaze, Duragesic, Lazanda, Abstral, Fentora, Subsys, OTFC, various)	Synthetic	CYP3A4/norfentanyl (inactive)	IM/IV	0.125[k]	7-15/3-4
			Transdermal, Buccal, transmucosal, sublingual, nasal, nebulized	Variable[l]	
Sufentanil (Sufenta, Dsuvia, various)	Synthetic	CYP3A4/norsufentanil (inactive)	IV/SL	0.030 (SL only)	30/2.5
Diphenylheptanes (methadone-like agonists)					
Methadone (Dolophine, various)	Synthetic	CYP3A4, CYP2B6, CYP2C19, CYP2C9, CYP2D6/EDDP (inactive)[m]	IM/IV	Variable[n] (acute)	
			PO	Variable[n] (acute)	30-60/12-190

Centrally Acting Agents					
Tramadol (Ultram, ConZip, various)	Synthetic	CYP3A4/nortramadol (inactive), CYP2D6/*O*-desmethyltramadol (active)	PO	50-100[g,o,p]	<60/5-7
Tapentadol (Nucynta)	Synthetic	Phase II glucuronidation/tapentadol-o-glucuronide (inactive), CYP2C9 and CYP2C19/*N*-desmethyltapentadol (inactive), CYP2D6/hydroxytapentadol	PO	50-10[h,o,p]	Within 60/4
Agonist–antagonist derivatives					
Pentazocine (Talwin, various)	Synthetic	Liver/Alcoholic and carboxylic acid derivatives (inactive), pentazocine glucuronide (inactive)	IM	Not recommended	
			PO	50[h]	15-30/2-3
Butorphanol (Stadol, various)	Synthetic	CYP3A4/hydroxybutorphanol (active), norbutorphanol (inactive)	IM/IV	2	10-20/3-4
			Intranasal	1[h] (one spray)	
Nalbuphine (Nubain, various)	Synthetic	CYP3A4 CYP2C19/nornalbuphine, 6-ketonalbuphine	IM/IV	10	<15/5
Buprenorphine (Buprenex, Butrans, Suboxone, Belbuca, Subutex, various)	Synthetic	CYP3A4/norbuprenorphine (active)	IM/IV	0.3	10-20/2-3
			Transdermal	Variable	
			Sublingual	Variable	

[a] The IM route should be avoided whenever possible—produces significant pain with administration and rate and extent of absorption is highly variable. If IV route is unavailable then administer subcutaneously (SC).

[b] ER/LA formulations may vary greatly in terms of onset and duration of analgesia. The reader should consult individual prescribing labels.

[c] Morphine-3-glucuronide (accumulates in renal failure).

[d] Morphine-6-glucuronide (accumulates in renal failure)

[e] Hydromorphone-3-glucuronide (accumulates in renal failure).

[f] Hydromorphone-6-glucuronide.

[g] Oxymorphone-3-glucuronide.

[h] Starting dose only (equianalgesia not shown).

[i] FDA approved as unhealthy use deterrent formulation.

[j] Starting doses lower (oxycodone 5-10 mg, meperidine 50-150 mg).

[k] Equivalent PO morphine dose = variable.

[l] For breakthrough pain only. Equianalgesic dose conversion should be avoided for Transmucosal Immediate Release Fentanyl (TIRF) products.

[m] 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidene (EDDP).

[n] The equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose. Caution should be exercised when initiating in opioid naïve patients.

[o] First day of dosing may administer second dose 1 hour after first dose.

[p] Onset of action may differ for long-acting formulations. Ceiling dose recommendations exist and may differ from immediate release dosing recommendations.

IM, intramuscular; IV, intravenous; PO, oral.

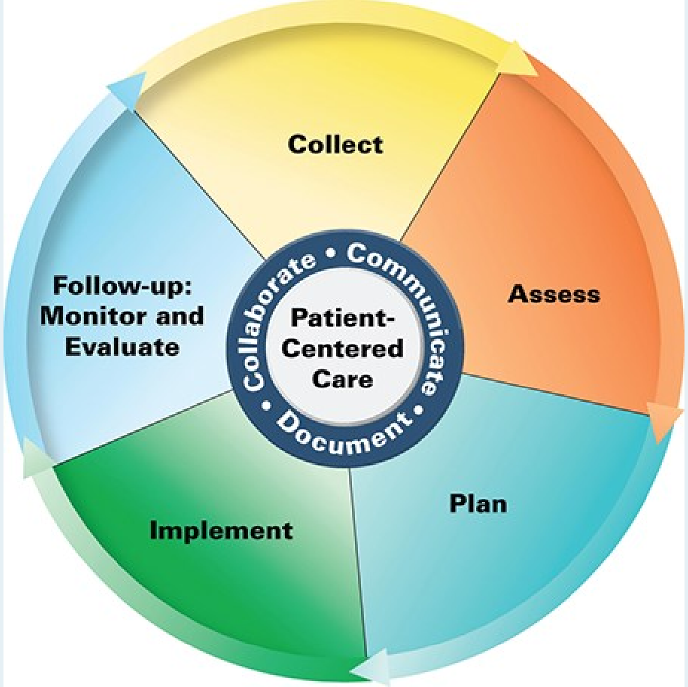
Data from References [53] *and* [61] *and individual product package inserts.*

Patient Selection Considerations in Chronic Noncancer Pain

③④⑤⑦⑧⑨⑩⑪ In all cases of chronic noncancer pain, an integrated systematic approach with a strong emphasis on patient–clinician relationships is essential. Patients and clinicians must realize that optimal treatment may take months or even years to achieve. Opioids are often a treatment of last resort in chronic noncancer pain and initiated as a time-limited trial to assess improvement in the patient's function, while overall tolerability is evaluated. Although long-term opioid therapy can be effective for individual patients in carefully considered situations, limited data exist to support such practice.[37,54] Chronic opioid therapy in this setting requires careful patient selection with judicious attention to risk factors (eg, person or family history of substance use disorder, younger age, male gender, and certain co-occurring mental health conditions) to evaluate the balance between potential benefit of therapy and the potential risks in the individual patient.

PATIENT CARE PROCESS

Patient Care Process for Pain Management



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient-specific characteristics (eg, age, gender, pregnancy status, race, and ethnicity)
- Pain and symptom-specific history (eg, onset, location, duration, characteristics, aggravating factors, alleviating factors, timing, severity, and impact on activities of daily living)
- Patient history including current and past medications, nonpharmacologic trials, allergies or medication intolerance, and pertinent social history (eg, tobacco, alcohol, or other substance use)
- Family history focusing on symptoms (ie, Rheumatoid arthritis) and social behavior (ie, substance use)
- Objective data including vitals, pertinent labs, targeted physical exam, and urine toxicology results

Assess

- Presence of co-occurring mental health conditions (ie, substance use disorder, depression, anxiety, or bipolar disorder) which may guide treatment decisions
- Data from prescription drug monitoring programs (PDMP), urine toxicology results, and validated risk screening or assessment tools
- Relative or absolute contraindications to the use of opioids, acetaminophen, antidepressants, antiseizure medications, nonsteroidal anti-inflammatory drugs (NSAIDs), or skeletal muscle relaxants
- Chronicity of pain symptom (eg, acute or chronic), likely etiology (eg, neuropathic, musculoskeletal, or visceral), and severity
- Patient willingness to engage in nonpharmacologic treatment modalities (eg, physical therapy, counseling, acupuncture, nerve blocks, or surgical interventions)

Plan*

- Patient and symptom-specific lifestyle modification (eg, weight loss, smoking cessation, self-pacing, and pain-trigger avoidance; see Table 79-2)
- Nonpharmacologic treatment modalities (see Table 79-3)

- Pharmacotherapy regimen including dose, route, frequency, and duration (see Table 79-4)
- Pharmacotherapy efficacy (analgesic and functional improvement), toxicity, and ongoing appropriateness using tools such as urine toxicology results, PDMP data, and risk assessment tools (see Table 79-6)
- Patient education on safe use, storage, disposal, and risk mitigation following formal Risk Evaluation and Mitigation Strategies when available (see Table 79-7)

Implement*

- Educate patient and/or caregiver regarding all elements of disease process and treatment plan, ensuring patient and/or caregiver understanding
- Informed consent, including pain or treatment agreements when necessary
- Schedule timely follow-up as guided by best practices in medication monitoring, following all appropriate regulations

Follow-Up: Monitor and Evaluate

- Attainment of treatment goals (eg, improved activity, improved sleep, improved work attendance)
- Presence of adverse effects
- Completion of validated ongoing risk assessment tools
- Frequent review of PDMP as clinically indicated and/or legally required
- Patient adherence to all facets of treatment plan, including nonpharmacologic modalities

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 79-6

Major Adverse Effects of the Opioid Analgesics

Effect	Manifestation
Mood changes	Dysphoria, euphoria
Somnolence	Sedation, inability to concentrate
Stimulation of chemoreceptor trigger zone	Nausea, vomiting
Respiratory depression	Decreased respiratory rate, periodic breathing, oxygen desaturation
Decreased gastrointestinal motility	Constipation
Increase in sphincter tone	Biliary spasm, urinary retention (varies among agents)
Histamine release	Urticaria, pruritus, rarely exacerbation of asthma due to bronchospasm(varies among agents)
Tolerance	Larger doses for same effect
Physical Dependence	Withdrawal symptoms upon abrupt discontinuation
Hypogonadism	Fatigue, depression, loss of analgesia, sexual dysfunction, amenorrhea
Sleep	Disrupts sleep–wake cycle, causes dose-dependent rapid eye movement (REM) suppression

Data from References [53,61].

TABLE 79-7

Key Recommendations of the Centers for Disease Control and Prevention Guideline for Prescribing Opioids for Chronic Pain

1. Nonpharmacologic and nonopioid modalities are preferred.
2. If opioid analgesia is warranted, establish realistic treatment goals.
3. Discuss the known risks and realistic benefits of opioid analgesics prior to initiation.
4. Immediate-release opioids are preferred over controlled release or long-acting (CR/LA) opioid formulations.
5. Use the lowest effective dose of opioid possible. Use caution at any dosage, and carefully reassess evidence of benefit versus risk when exceeding ≥50 MME/day and avoid increasing dose ≥90 MME/day without careful justification.
6. Opioid analgesia should be used for the shortest duration possible. In most cases, 3 days is sufficient for acute pain. More than 7 days will rarely be required for most acute pain indications.
7. Clinicians should regularly evaluate the benefits and harms of ongoing opioid analgesia within 1 to 4 weeks of initiation and at least every 3 months when ongoing opioid therapy is required. Consider taper and discontinuation when harm risk outweighs benefit potential.
8. Careful evaluation of opioid overdose risk should be assessed frequently, and naloxone co-prescribed at opioid doses of ≥50 MME/day or when patients are exposed to concurrent opioid and benzodiazepines.
9. Prescription drug monitoring programs should be reviewed at opioid initiation and periodically, ranging from every prescription to at least every 3 months.
10. Clinicians should use urine toxicology results prior to initiating opioid therapy and periodically when ongoing therapy is warranted.
11. Concurrent prescribing of opioid analgesics and benzodiazepines should be avoided when possible.
12. When opioid use disorder is recognized or suspected, clinicians should offer evidence-based treatment such as pharmacotherapy (ie, methadone or buprenorphine/naloxone) in combination with behavioral therapies.

MME, morphine milligram equivalent; CR, controlled release; LA, long acting.

Data from Reference [37].

Nonopioid Analgesics

Acetaminophen and Nonsteroidal Anti-inflammatory Drugs

⑤⑥⑦Analgesics should be initiated with the most effective agent having the fewest potential adverse effects. Acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are often preferred first-line therapies in the treatment of mild-to-moderate pain, although the efficacy of acetaminophen has been called into question (Table 79-8).[55,56] The exact mechanism of acetaminophen is not completely understood but likely involves central prostaglandin modulation.[57] The NSAIDs inhibit formation of varying prostaglandins produced in response to noxious stimuli, thereby decreasing neuronal pain transmission received by the CNS.[40] While acetaminophen is still considered a first-line therapy for some mild pain conditions, in some pain-related disease states, such as osteoarthritis, NSAIDs, either oral or topical, may be preferred.[58,59] In addition, NSAIDs are recommended after nonpharmacologic therapy failure for acute, subacute, and chronic low back pain.[60]

TABLE 79-8

Nonopioid Analgesics

Class and Generic Name (Brand Name)	Approximate Half-Life (h)	Usual Dosage Range (mg)	Maximal Dose (mg/day)
Salicylates			

Acetylsalicylic acid[a]—aspirin (various)	0.25	325-1,000 every 4-6 hours	4,000
Diflunisal (Dolobid, various)	8-12	500-1,000 initial 250-500 every 8-12 hours	1,500
Salsalate (various)	1	1,000 every 12 hours or 500 every 6 hours	3,000
***Para*-aminophenol**			
Acetaminophen[a] (Oral: Tylenol, various; Parenteral: Ofirmev)	2-3	325-1,000 every 4-6 hours	4,000[b] Dosing for peds lower based on weight
Fenamates			
Meclofenamate (various)	0.8-3.3	50-100 every 4-6 hours	400
Mefenamic acid (Ponstel)	2	Initial 500, 250 every 6 hours (max. 7 days)	1,000[c]
Pyranocarboxylic acid			
Etodolac (various) (immediate release)	7.3	200-400 every 6-8 hours	1,000-1,200 with extended-release product
Acetic acid			
Diclofenac potassium (Cataflam, various, Flector [patch] Voltaren Gel, Pennsaid [solution])	1.9	In some patients, initial 100, 50, 3 times per day Patch available: to be applied twice daily to painful area (intact skin only), gel and solution dosing joint specific	150[d]
Propionic acids			
Ibuprofen[a] (Motrin, Caldolor, various)	2-2.5	200-400 every 4-6 hours Injectable, 400-800 every 6 hours (infused over 30 minutes)	3,200,[e] 2,400,[e] 1,200[f]
Fenoprofen (Nalfon, various)	3	200 every 4-6 hours	3,200
Ketoprofen (various)	2	25-50 every 6-8 hours	300 200 with extended-release product
Naproxen (Naprosyn, Anaprox, various)	12-17	500 initial 500 every 12 hours or 250 every 6-8 hours	1,000[c]

Naproxen sodium[a] (Aleve, various, combined with esomeprazole [Vimovo])	12-17	In some patients, 440 initial[f] 220 every 8-12 hours[f]	660[f]
Pyrrolizine carboxylic acid			
Ketorolac–parenteral (Toradol, various)	5-6	30[g]-60 (single IM dose only)	30[g]–60
		15[g]-30 (single IV dose only)	15[g]–30
		10[g]-30 every 6 hours (IV dose) (max. 5 days)	60[g]-120
Ketorolac—oral, indicated for continuation with parenteral only (various)	5-6	10 every 4-6 hours (max. 5 days, which includes parenteral doses)	40
Ketorolac—nasal spray, indicated for acute, moderate to moderately severe pain		1 spray (15.75 mg) in each nostril every 6-8 hours in adults <65 years of age and weight ≥50 kg	126
		1 spray (15.75 mg) in one nostril every 6-8 hours in adults >65 years of age or weight <50 kg	
Pyrazols			
Celecoxib (Celebrex)	11	Initial 400 followed by another 200 on first day, then 200 twice daily (note some recommend maintenance doses of 200 mg/day due to cardiovascular concerns)	400

[a] Available both as an over-the-counter preparation and as a prescription medication.

[b] Food and Drug Administration maximum dose. OTC maximum dose 3,000 mg daily. Lower with weight-based dosing in pediatric patients.

[c] Up to 1,250 mg on the first day.

[d] Up to 200 mg on the first day.

[e] Some individuals may respond better to 3,200 mg as opposed to 2,400 mg, although well-controlled trials show no better response; consider risk versus benefits when using 3,200 mg/day.

[f] Over-the-counter dose.

[g] Dose for older patients and those under 50 kg (110 lb).

FDA, Food and Drug Administration; h, hours; IM, intramuscular; IV, intravenous; ND, no data.

Data from References [53,61].

⑥⑦⑧Studies comparing the efficacy of individual NSAIDs have failed to identify differences in efficacy. Therefore, the choice of a particular agent often depends on availability, cost, pharmacokinetics, pharmacologic characteristics, and the adverse effects. Because of the large interpatient variability in response to individual NSAIDs, it is considered rational therapy to switch to another member of this class if there is inadequate response after a sufficient therapeutic trial of any single agent.[53] The duration of a sufficient trial has not been well defined; however, typically, an NSAID should be continued for a minimum of 1 month prior to evaluating the need to switch agents. Chronic use of NSAIDs may result in serious gastrointestinal (GI), renal, and cardiac toxicity and to a lesser extent liver toxicity. Topical NSAIDs may offer similar efficacy as oral NSAIDs with improved safety and tolerability in the treatment of small or superficial joint arthritis.[62] Appropriate patient selection for NSAID therapy is critical to ensure optimal benefit while minimizing potential adverse effects. Several NSAIDs are subject to pharmacogenomic variants.[63]

Co-Analgesics

⑤⑥⑦Co-analgesics represent a diverse group of pharmacologic agents with individual characteristics that make them useful in the management of pain, but these agents typically are not classified as analgesics. Chronic pain that has a neuropathic component (eg, diabetic neuropathy) often requires co-analgesic therapy. Antiseizure medications (eg, gabapentin, pregabalin, which may decrease neuronal excitability), tricyclic antidepressants and serotonin and norepinephrine reuptake inhibitor antidepressants (eg, duloxetine, venlafaxine—which block the reuptake of serotonin and norepinephrine, thus enhancing pain inhibition), and topically applied local anesthetics (which decrease nerve stimulation) all have demonstrated efficacy in managing various chronic pain conditions.[64]

Antiseizure Medications

⑥⑦⑧The antiseizure medications frequently employed for pain are presented in Table 79-9.[65–72] Carbamazepine and oxcarbazepine block voltage-gated sodium channels and potentiate the effects of GABA and are considered the agents of choice for trigeminal neuralgia according to multiple guidelines.[64,66,73,74] The primary metabolic pathway for carbamazepine is CYP3A4. The active metabolite, carbamazepine 10,11-epoxide, auto-induces its own metabolism, making titration difficult. Carbamazepine is associated with many medication interactions through induction of CYP3A4, CYP1A2, CYP2B6, CYP2C9, and CYP2C19. Common adverse effects during initiation include dizziness, drowsiness, unsteadiness, nausea, and vomiting and can be avoided with low starting doses. There are rare cases of aplastic anemia and agranulocytosis associated with carbamazepine use, so a complete blood count (CBC) should be monitored during therapy. Hyponatremia is also reported, which requires regular monitoring of sodium.[75] Cardiovascular effects include hyper/hypotension, congestive heart failure, edema, arrhythmias, and atrioventricular block. Hepatic enzymes should be monitored periodically during the treatment for potential elevation.[76]

TABLE 79-9

Co-Analgesics: Antiseizure Medications

Medication	Mechanism of Action	Role	Dosing	Notes
Carbamazepine and carbamazepine XR	Inhibits voltage-gated sodium channels, potentiate GABA	• Trigeminal neuralgia • Neuropathic pain	• Initial dose: 100 mg PO BID • Titrate dose by 100 mg PO BID • Target dose: 300–900 mg/day • Maximum dose: 1,200 mg/day	• Significant medication interactions • Monitor CBC, LFTs, sodium level • Recommended testing HLA-B*15:02[a] HLA-A*31:02 in patients with Asian ancestry • Therapeutic medication levels only indicated for high-dose therapy to avoid toxicity. No correlation between analgesia and serum medication concentration
Gabapentin	Inhibition α2δ subunit of the voltage-gated calcium channel leading to decreased release of excitatory neurotransmitters including glutamate, norepinephrine, and	• PHN[a] • Neuropathic pain • Perioperative	• 100-300 mg steps • Increase every 3-5	• Median dose for response 1,600-2,400 mg/day • Risk for substance use disorder • Requires renal dose adjustment

	substance P	pain	days as tolerated by 100-300 mg increments	
Gabapentin (Gralise)	Refer to gabapentin	PHN[a]	- Take once daily with evening meal - Day 1: 300 mg - Day 2: 600 mg - Day 3-6: 900 mg - Days 7-10: 1,200 mg - Days 11-14: 1,500 mg - Day 15: 1,800 mg - Maximum dose: 1,800 mg/day	Refer to gabapentin
Gabapentin enacarbil	Refer to gabapentin	- PHN[a] - Restless leg syndrome (RLS)[a]	- Initial dose: 600 mg PO QAM × 3 days - Titrate dose: 600 mg PO BID - Maximum dose: 1,200 mg/day	Refer to gabapentin
Lamotrigine	Inhibits sodium channels	Neuropathic pain (Fourth line Canadian NP guidelines, specialist setting NICE guidelines)	- Initial 25 mg PO daily - Titrate q2weeks to 50 mg/day, 100 mg/day, and 200 mg/day - Maximum dose: 400 mg/day	Stevens–Johnson syndrome
Oxcarbazepine	Inhibits sodium channels	- Trigeminal neuralgia (EFNS) - Neuropathic	- Initial: 150 mg PO BID - Titrate by 300	- Improved tolerability and less medication interactions compared to CBZ

		pain (specialist setting NICE guidelines)	mg q3 days • Target dose: 300-600 mg BID • Max dose: 1,800 mg/day	• Pharmacogenomic testing recommended in Asian patients due to *HLA-B*15:02* variant
Oxcarbazepine XR	Refer to oxcarbazepine	(See above under oxcarbazepine)	• Initial dose: 600 mg PO daily • Titrate by 600 mg/day weekly • Maximum: 2,400 mg/day	Refer to oxcarbazepine
Pregabalin	Refer to gabapentin	• DPN[a] • Fibromyalgia[a] • Neuropathic pain associated with spinal cord injury[a] • Neuropathic pain • PHN[a] • Perioperative pain	• Initial dose: 150 mg/day in two or three divided doses • Titrate dose by 300 mg/day at 1 week • Maximum dose: varies by indication. Overall 600 mg/day	Refer to gabapentin
Pregabalin CR	Refer to gabapentin	• DPN[a] • PHN[a]	• Initial dose: 165 mg daily • Maximum dose: 330 mg/day (DPN) or 330-660 mg/day (PHN)	Refer to gabapentin
Topiramate and Topiramate XR	Inhibits voltage-gated sodium channels, AMPA/kainite subtype of glutamate receptor, and carbonic anhydrase; increases activity of GABA-A receptor	• Alcohol use disorder • Migraine prophylaxis • Neuropathic pain (fourth-line Canadian NP guidelines, specialist setting	• Initial dose: 25 mg PO daily × 1 week • Titrate by 25-50 mg week • Target dose: 50 mg PO BID (migraine ppx) or 200-	• Monitor serum bicarbonate and renal function • Increase risk for kidney stones • Weight loss • Decreased sweating/hyperthermia • Hyperammonemia • Paresthesias • Cognitive dulling

		NICE guidelines)	400 mg/day neuropathic pain	

[a] FDA-approved indication.

All anticonvulsants associated with increased risk for suicidal thoughts and behaviors.

Data from References [61,65].

Oxcarbazepine is the keto derivative of carbamazepine and is metabolized to an active metabolite, 10-monohydroxy oxcarbazepine, which does not undergo Phase I metabolism in the liver. This is advantageous for oxcarbazepine with reduced medications interactions and adverse effects compared to carbamazepine.[76] The most common adverse effects include dizziness, somnolence, diplopia, fatigue, nausea, vomiting, ataxia, abnormal vision, headache, nystagmus, tremor, and abnormal gait. Other adverse effects include hyponatremia, angioedema or anaphylactic reactions, pancytopenia, agranulocytosis, and leukopenia.[75] In addition to its role in trigeminal neuralgia, the National Institute for Health and Care Excellence (NICE) guidelines list oxcarbazepine for the treatment of neuropathic pain in a specialist setting as fourth-line treatment.[64,74,77]

Gabapentinoids, including gabapentin and pregabalin, are common antiseizure medications used in the treatment of neuropathic pain. There are numerous formulations available with varying indications that may include diabetic peripheral neuropathy (DPN), postherpetic neuralgia (PHN), fibromyalgia, neuropathic pain associated with spinal cord injury (SCI), and restless legs syndrome (RLS). Based on several neuropathic pain treatment guidelines, gabapentinoids are considered first-line medications for the treatment of neuropathic pain.[64–67,74] Other roles for gabapentinoids include perioperative pain management as a part of a multimodal approach or “enhanced recovery after surgery” (ERAS) protocols. These agents, however, were not included in the ERAS Society guidelines due to inconclusive evidence.[78] In general, evidence has not supported the use of gabapentinoids for the prevention of chronic post-surgical pain.[78,79] There are negative findings for pregabalin in acute and chronic sciatica as well as gabapentin and pregabalin for nonspecific low back pain.[80,81]

Gabapentinoids do not, as their name may suggest, alter GABA binding, uptake, metabolism, or degradation though their pharmacology does lead to GABA-mimetic effects. Primary pharmacodynamic effects are due to the inhibition of voltage-gated calcium channels specifically by binding to the presynaptic α2δ subunit. This results in decreased release of excitatory neurotransmitters glutamate, norepinephrine, and substance P.[70]

Common adverse medication effects, namely dizziness and sedation, can be mitigated with slow dose titration. Gabapentinoids may lead to peripheral edema and weight gain which may be dose-limiting adverse effects. All antiseizure medications have been associated with increased risk for suicidal thoughts and behavior. There have been increasing reports of unhealthy gabapentinoid use, which has resulted in some states classifying them as controlled substances and including them in their PDMPs.[82,83] Gabapentionoids are cleared renally and have recommended renal dose adjustments as well as supplemental doses after hemodialysis.[84]

Several neuropathic pain guidelines place lamotrigine as a fourth-line agent or medication for use in a specialist setting.[64,66,74] The mechanism of action of lamotrigine is not entirely known but thought to be related to the inhibition of voltage-gated sodium channels. One of the main concerns with the use of lamotrigine is the possibility of life-threatening rash. To minimize the risk of a rash, the dose is titrated slowly (ie, every 2 weeks). If any signs of rash appear, lamotrigine should be discontinued immediately, although other fatal or life-threatening hypersensitivity reactions can occur as lamotrigine is also associated with blood dyscrasias and aseptic meningitis. More common adverse effects include dizziness, nausea, headache, insomnia, somnolence, fatigue, rhinitis, abdominal pain, diplopia, ataxia, and blurred vision. Utilizing lamotrigine is further complicated by the potential for multiple medication interactions.

For neuropathic pain, topiramate is listed as a fourth-line agent by the Canadian Pain Society guideline and for use in specialist settings by the NICE guidelines.[66,74] Additionally, topiramate has been evaluated for radicular low back pain in two small studies with conflicting data on benefits versus risk.[85,86] It has four components to its proposed mechanism of action including inhibition of voltage-gated sodium channels, increased effects of $GABA_A$ receptors, blocking AMPA/kainate subtype of glutamate receptors, and inhibiting the carbonic anhydrase enzyme. Topiramate has numerous warnings and precautions including secondary angle closure glaucoma, metabolic acidosis, hyperammonemia/encephalopathy, kidney stones, oligohidrosis, hypo/hyperthermia, and cognitive dysfunction. Renal dose adjustments are recommended with a creatinine clearance (CrCl) <70 mL/min (1.17 mL/s), and topiramate is removed via hemodialysis, so supplemental doses are needed. Dose-related adverse effects include paresthesia, fatigue, nausea, anorexia, dizziness, difficulty with memory, diarrhea, weight loss, concentration/attention problems, and somnolence.

Antidepressants

⑥ ⑦ ⑧ Select antidepressants have long been used for their anti-nociceptive effects (Table 79-10).[61,65,87] In general, the tricyclic antidepressants (TCAs) are often used for the treatment of neuropathic pain. According to the Canadian Pain Society, the Neuropathic Pain Special Interest (NeuPSIG) from the International Association of the Study of Pain, and the European Federation for Neurological Societies (EFNS), TCAs are first line options for neuropathic pain.[63–65] The NICE guidelines lists amitriptyline as a first-line option for neuropathic pain.[64–66] Interestingly, the American Diabetes Association does not list TCAs as first-line because they are not FDA approved for this indication.[67] Other evidence-based uses of TCAs include low back pain, fibromyalgia, and migraine prophylaxis.[69]

TABLE 79-10

Co-Analgesics: Antidepressants

Medication	Mechanism of Action (MOA)	Role	Dosing	Notes
Tricyclic antidepressants (TCA)				
• Amitriptyline • Desipramine • Imipramine • Nortriptyline	• Inhibit reuptake serotonin and norepinephrine which in turn inhibit descending pain pathway • Analgesic effects independent of antidepressant effects and lower doses needed for analgesic effects compared to MDD doses	• Fibromyalgia • Low back pain • Migraine prophylaxis • Neuropathic pain	• Initial: 10-25 mg PO QHS • Titrate by 10-25 mg q3-7 days • Maximum: 150 mg	• Secondary amines (desipramine, nortriptyline) less anticholinergic activity = less ADE • Multiple cardiac AME (including QTc prolongation, orthostatic hypotension, arrhythmias, tachycardia) • Doses > 100 mg/day associated with sudden cardiac death • Lowers seizure threshold • Impacted by Pharmacogenomics
Serotonin norepinephrine reuptake inhibitors (SNRI)				
Duloxetine	• Inhibits reuptake serotonin and norepinephrine which in turn inhibits descending pain pathway • Analgesic effects independent of antidepressant effects	• Chronic musculoskeletal pain (low back pain [LBP], osteoarthritis)[a] • Diabetic	• Initial: 30 mg PO daily × 1 week (2 weeks if an older patient) • Target dose: 60 mg PO daily • Maximum dose: 120	• Avoid eGFR < 30 mL/min (0.50 mL/s) • Avoid chronic liver disease or cirrhosis • Hypertension • Hyponatremia

		peripheral neuropathy (DPN)[a] • Fibromyalgia[a] • Chemotherapy-induced neuropathic pain (CINP)	mg/day though limited evidence for doses >60 mg providing additional benefit in pain	• Increased risk of bleeding (GI and CNS)
Milnacipran	• Inhibits reuptake serotonin and norepinephrine which in turn inhibits descending pain pathway • Analgesic effects independent of antidepressant effects	Fibromyalgia[a]	• Day 1: 12.5 mg PO daily • Days 2-3: 12.5 mg PO BID • Days 4-7: 25 mg PO BID • Then increase to 50 mg PO BID • Target dose: 100 mg/day • Maximum dose: 200 mg/day	• Avoid eGFR <30 mL/min (0.50 mL/s) • Caution with severe hepatic impairment • Increase risk for bleeding
Venlafaxine	• Inhibits reuptake serotonin and norepinephrine which in turn inhibits descending pain pathway • Analgesic effects independent of antidepressant effects	• CINP • DPN • Fibromyalgia • LBP • Migraine prophylaxis • Painful polyneuropathy • Tension-type headache	• Initial: venlafaxine SA 37.5 mg PO daily • Titrate: by no more than 75 mg/day q4 days • Maximum dose: 225 mg/day	• Higher doses needed to achieve SNRI effect • Dose adjustments with renal/hepatic impairment • Hypertension • Hyponatremia • QTc prolongation • Increased bleeding risk

[b]FDA-approved indication(s).

AME, adverse medication effect.

Data from References [61, 65, 87].

TCAs exert their effects through inhibition of serotonin and norepinephrine reuptake that enhances the descending inhibitory pain pathway, often at doses significantly less than used for the treatment of depression.[69] Additionally, TCAs interact with and inhibit acetylcholine muscarinic receptors, alpha-adrenergic receptors, histamine-1 receptors, and voltage-gated sodium channels, all of which contribute to their many adverse effects.[88,89] Notably, TCAs can be divided into two different subgroups—tertiary amines (eg, amitriptyline and imipramine) and secondary amines (eg, nortriptyline and desipramine) with the tertiary amines being metabolized to secondary amines. Secondary amines interact with fewer receptors associated with adverse effects and provide similar analgesic efficacy.[70] TCAs are also impacted by pharmacogenomic variants though existing guidelines focus on the role of TCAs for depression with a small section discussing neuropathic pain (See Personalized Pharmacotherapy section).[90]

The major downfall with TCAs is their adverse effect profile, as they are associated with slowed cardiac conduction, QTc prolongation, arrhythmias, tachycardia, and orthostatic hypotension. Doses of TCAs in excess of 100 mg/day have been associated with sudden cardiac death.[91] There are varying recommendations regarding electrocardiogram monitoring with TCAs but may be appropriate in patients greater or equal to 40 to 50 years of age prior to starting and periodically during continued use.[70,91] Anticholinergic effects are another major issue with TCAs and often preclude their use in patients with benign prostatic hypertrophy, glaucoma, or cognitive impairment. Sedative effects, owing to their inhibition of histamine receptors, may be unwanted in some patients, though desired in patients with insomnia; thus, TCAs are typically given at bedtime.

Duloxetine, venlafaxine, and milnacipran are serotonin norepinephrine reuptake inhibitors (SNRIs) that are either FDA-approved or have evidence to support their use in various chronic pain syndromes. Similar to TCAs, SNRIs inhibit the reuptake of serotonin and norepinephrine and modulate the descending pain pathway. Though a mental health diagnosis is not needed for analgesic benefit, SNRIs may be particularly useful in those with mental health comorbidities as doses used for pain are frequently similar to those used for mental health conditions. In addition to major depressive disorder (MDD) and generalized anxiety disorder (GAD), duloxetine is FDA-approved for fibromyalgia, chronic musculoskeletal pain (low back pain and osteoarthritis), and diabetic peripheral neuropathic pain. The American College of Physicians' guideline for low back pain recommends duloxetine as a second-line medication for those that fail nonpharmacological approaches and NSAIDs.[60] Venlafaxine is not FDA-approved for any pain diagnoses; however, there is evidence supporting the use of venlafaxine for neuropathic pain, low back pain, fibromyalgia, migraine prophylaxis, and tension-type headache prophylaxis.[68,92–96] Duloxetine and venlafaxine are considered first-line options for neuropathic pain according to several neuropathic pain guidelines.[64–67,73] Milnacipran is FDA approved for fibromyalgia syndrome only.[97]

More likely adverse effects of SNRIs include nausea, somnolence, dry mouth, anorexia, erectile dysfunction, and constipation. Seizures, hyponatremia, and worsening of acute angle closure glaucoma may also occur. Because SNRIs impact norepinephrine, transient elevations in blood pressure should be anticipated. Therefore, it is important to ensure optimal blood pressure control prior to initiation and ongoing monitoring during therapy. In addition, venlafaxine has been associated with QTc prolongation, so caution is advised in those with cardiovascular disease or risk factors for QTc prolongation.[98] There are no agreed upon recommendations for QTc monitoring with venlafaxine. All SNRIs have liver and renal considerations; however, the specific criteria vary among the different SNRIs. Furthermore, SNRIs interfere with platelet aggregation and increase risk for bleeding, particularly when combined with NSAIDs, anticoagulants, or corticosteroids. This risk of gastrointestinal bleeding can be reduced with concomitant proton pump inhibitors use.[99]

Skeletal Muscle Relaxants

⑥⑦⑧ Skeletal muscle relaxants (SMRs) are composed of antispasmodic and antispasticity medications (Table 79-11).[61,100–104] Diazepam and Tizanidine have properties of both categories. Spasticity and spasms have several differences including etiology, symptoms, and causes.[105]

TABLE 79-11

Skeletal Muscle Relaxants

Medication	Role	Mechanism of Action	Dosing	Notes
Baclofen	Antispasticity	Related to GABA, works at spinal cord, inhibits polysynaptic and monosynaptic reflexes	• Initial: 5 mg PO TID Initial: 5 mg PO TID • Titrate: q3 days to effect • Maximum: 80 mg/day	• Withdrawal syndrome (hallucinations, seizures) • Respiratory depression • Requires renal dose adjustment
Carisoprodol	Antispasmodic/antispasticity	• Centrally acting, changing interneuronal activity in descending reticular formation and spinal cord • Meprobamate (primary metabolite) leads to barbiturate effects at $GABA_A$	250-300 mg four times daily	• Meprobamate (a barbiturate) is primary metabolite and has physical dependence potential

				- Schedule IV controlled substance - Withdrawal syndrome - Respiratory depression with opioids, benzodiazepines, or barbituates - Metabolized by CYP2C19 which has genetic variabilities
Chlorzoxazone	Antispasmodic	Works in spinal cord and subcortical areas of brain by inhibiting multisynaptic reflex arcs	- Initial: 250-500 mg three to four times daily - Maximum dose: 750 mg three to four times daily	- Rare hepatotoxicity - Urine discoloration - Respiratory depression when combined with opioids, benzodiazepines, or barbiturates
Cyclobenzaprine	Antispasmodic	Structurally related to TCAs, sedative effects, works at brainstem level, decreases excitability of alpha and gamma motor neurons	- Initial: 5 mg PO TID - Titrate: increase to 7.5-10 mg TID × 2-3 weeks - Older patients: 5 mg dose with less frequent doses - Doses used in fibromyalgia 10 mg QAM, 20 mg QHS	- Anticholinergic effects - Avoid in older patients - Caution in patients with cardiac conduction/arrhythmias - Avoid closed angle glaucoma - Hepatic dose adjustments
Diazepam	Antispasmodic/antispasticity	Postsynaptic inhibition of GABA neurons in spinal cord	Adults: 2-10 mg three to four times daily	- Long half-life - Avoid in older patients and those renal/hepatic impairment - Withdrawal with abrupt discontinuation

Methocarbamol	Antispasmodic	Unknown, sedative properties	• Initial: 1,500 mg PO four times daily × 2-3 day • Then: 750-1,000 mg PO four times daily	• Urine discoloration • Respiratory depression with opioids, benzodiazepines, or barbiturates
Metaxalone	Antispasmodic	Unknown, sedative properties	800 mg PO three to four times daily	• Respiratory depression when used with opioids, benzodiazepines, or barbiturates • Contraindicated in severe liver/renal impairment
Orphenadrine	Antispasmodic	Unknown, suspect analgesic and anticholinergic effects, H_1 receptor antagonist, NMDA receptor antagonist	100 mg PO BID	• Anticholinergic effects • Rare aplastic anemia
Tizanidine	Antispasmodic/antispasticity	Centrally acting α-2 agonist, inhibits presynaptic motor neurons, decreases polysynaptic reflex and abnormal contraction of opposing muscle groups	• Initial: 4 mg • Titrate by 2-4 mg q6-8 h • Maximum: 36 mg/day	• Hypotension • Hepatotoxicity • Tablets and capsules not bioequivalent • Withdrawal syndrome with abrupt discontinuation

Data from References [61,105].

Spasticity involves an upper motor neuron disorder.[105] Symptoms include stiffness, hypertonicity, and hyperreflexia.[105] Causes of spasticity include multiple sclerosis, cerebral palsy, spinal cord injury, traumatic brain injury, and post-stroke syndrome.[105] Medications used for spasticity include baclofen, dantrolene, diazepam, and tizanidine.

Baclofen is similar in structure to GABA and binds to $GABA_B$ receptors. These receptors are coupled to Ca^{2+} and K^+ channels located pre- and post-synaptically. Essentially this leads to reduction in the release of excitatory glutamate and increases presynaptic inhibition. Additionally, baclofen may reduce the release of substance P. Sedation, dizziness, weakness, and nausea are possible adverse effects, with the most concerning being associated with baclofen as hallucinations or seizures may occur during withdrawal with abrupt discontinuation. Therefore, baclofen must be tapered slowly.[105] Baclofen also requires dose adjustment for decreased renal function.[106]

Diazepam is not often used for non-cancer pain because of its sedative effects and potential for physical dependence. It's mechanism of action involves binding to $GABA_A$ resulting in increased chloride conductance which subsequently leads to presynaptic inhibition of the spinal cord. Abrupt discontinuation of diazepam can lead to a withdrawal syndrome, namely seizures. Diazepam has a long half-life (20-50 hours for parent and up to 100 for active metabolites) which is problematic especially for older patients. Avoid the use of diazepam in patients with renal or hepatic impairment.[105]

Similar to diazepam, tizanidine has both antispasticity and antispasmodic uses and is a centrally acting α_2-agonist. Pre-synaptically, tizanidine inhibits the release of excitatory neurotransmitters that leads to a reduction in postsynaptic activation of the upper motor neuron. In addition, tizanidine leads to the potentiation of glycine. Not surprisingly, because of its α_2-agonist activity, hypotension can occur and rebound hypertension seen with abrupt discontinuation. Other significant issues with tizanidine include sedation and elevation in hepatic enzymes requiring periodic monitoring. Tizanidine is metabolized by CYP1A2 and is contraindicated in combination with ciprofloxacin or fluvoxamine.[105,107]

Spasms are involuntary contractions of the muscle and antispasmodics treat musculoskeletal conditions and symptoms like jerks, twitches, and cramps.[105,107] Associated causes include musculoskeletal pain, fibromyalgia, mechanical low back pain, sciatica, disc herniation, and myofascial pain.[105] Skeletal muscle relaxants or NSAIDs are recommended as pharmacologic treatment for patients with acute or subacute low back pain.[60] While studies suggest SMRs are associated with a small increase in pain relief, there is no evidence to support improvement in function with SMRs.[60] Importantly, SMRs should be used short-term. If used long-term, SMRs may increase the risk for adverse effects and polypharmacy, particularly in older patients, as many appear (like other medications used to manage pain) on the Beer's List of Potentially Inappropriate Medications for Use in the Elderly from the American Geriatrics Society.[108,109] Antispasmodics include carisoprodol, chlorzoxazone, cyclobenzaprine, diazepam, metaxalone, methocarbamol, orphenadrine, and tizanidine.

Carisoprodol is a Schedule IV controlled substance and is metabolized via CYP2C19 to meprobamate, a barbiturate. Because of its barbiturate activity, carisoprodol has the potential for physical dependence. It is centrally acting and changes interneuronal activity in the descending reticular formation and spinal cord. Meprobamate has activity at GABA_A receptors, and withdrawal can occur with abrupt discontinuation. Furthermore, respiratory depression can occur when combined with opioids, benzodiazepines, or barbiturates.[105,107]

Chlorzoxazone blocks multisynaptic reflex arcs in the spinal cord and subcortical areas of the brain. Sedation is a common effect and rare adverse effects include hepatotoxicity or GI bleeding. If used chronically, hepatic transaminase monitoring is recommended. Urine discoloration may be experienced and respiratory depression may occur when combined with opioids, benzodiazepines, or barbiturates.[105,107]

Structurally, cyclobenzaprine is similar to the TCAs. It is thought to exert its effects through decreasing the excitability of alpha and gamma motor neurons while also leading to CNS depression through the brain stem. Anticholinergic adverse effects are common and should be used with caution in those with cardiac arrhythmias or conduction disturbances. Cyclobenzaprine should be avoided in those with acute narrow angle glaucoma and those of older age. With mild hepatic impairment, dose adjustments are recommended and cyclobenzaprine should be avoided in those with moderate-to-severe hepatic impairment.[105,107]

The mechanism of action of metaxalone is unclear as it has no activity on skeletal muscle or nerve fibers. Thus, it is suspected that its effects are primarily due to CNS depression. Metaxalone is metabolized through multiple CYP enzymes including CYP1A2, CYP2D6, CYP2E1, and CYP3A4. In those with severe renal or hepatic impairment, metaxalone should be avoided. Rare adverse effects of metaxalone include leukopenia, hemolytic anemia, or hepatic transaminase elevation. Again, respiratory depression can occur when combined with opioids, benzodiazepines, or barbiturates.[105,107]

Similar to metaxalone, the mechanism of action of methocarbamol is unknown and suspected to be associated with its sedative properties. Respiratory depression can occur when used concomitantly with other medications. Urine discoloration (brown, green, black) is also possible.[105,107]

Orphenadrine is structurally related to diphenhydramine and possesses comparatively higher anticholinergic effects. Yet again, the mechanism of action is not completely elucidated and conjectured due to its sedative and anticholinergic effects. Orphenadrine also inhibits histamine-1 and NMDA receptors. With orphenadrine, GI irritation may occur and there is a rare incidence of aplastic anemia. It should be avoided in those with glaucoma, myasthenia gravis, or cardiospasm. Because of the anticholinergic effects, it should be avoided in older patients. It has a relatively long half-life ranging from 13 to 20 hours. Its CNS depressant effects are magnified when used with other CNS depressants.[105,107]

Topicals

⑥⑦⑧⑨The advantages of topicals include addressing local symptoms while minimizing systemic exposure and risk for adverse effects (Table 77-10).[110,111] According to the NICE osteoarthritis guidelines, topical NSAIDs should be considered for knee or hand OA before a trial of oral NSAIDs.[112] The American College of Rheumatology (ACR) guidelines for hand, hip, and knee OA also strongly recommend topical NSAIDs for knee OA and conditionally for hand OA. Additionally, topical capsaicin may be considered as an adjunct to core treatments for hand and knee osteoarthritis according to the NICE guidelines although ACR conditionally recommends against capsaicin in hand OA, while recommending conditionally for capsaicin use in knee OA.[58,112] Capsaicin appears in several neuropathic pain guidelines as either second-line, third-line, or fourth-line for various peripheral neuropathic pain syndromes.[64–66,74] Capsaicin activates transient receptor potential vanilloid 1 (TRPV1) channels. There are various over-the-counter and prescription strength products available. Burning may occur with initial application and that this decreases over time with repeated, scheduled use. Capsaicin is not recommended for "as needed" use as repeated application is needed to desensitize C-fibers. The capsaicin 8% patch is FDA approved for several neuropathic pain syndromes and is to be administered under the direct supervision of a physician. There are specific administration directions in the packaging information including pretreatment of the area with topical anesthetic. Topical medications should not be applied to open skin. The NICE guidelines recommend against the use of rubefacients for osteoarthritis.[112] Lidocaine is also used topically and works by inhibiting voltage-gated sodium channels. For PHN, one guideline places lidocaine as a first-line option and may even be preferred over other first-line options in older patients when CNS adverse effects are of concern.[63] Other guidelines list topical lidocaine as second-line or fourth-line options for neuropathic pain.[65,66] Table 79-16 includes commonly used topical analgesics.

Emerging Agents

Two agents have received widespread attention for their potential analgesic benefit, namely cannabis and ketamine. Medical cannabis has been studied primarily in neuropathic pain conditions with equivocal results. Route of administration, dose, and monitoring recommendations are still unclear. More importantly, research on the specific cannabinoids and terpenes present in many of the *cannabis* strains is required considering the widely variable pharmacologic profiles of these substances.[113,114] The non-psychoactive cannabinoid, *cannabidiol* (CBD) may have a significant role in the treatment of chronic pain, although its utility in the absence of delta-9-tetrahydrocannabinol (THC) is unclear.[115,116]

Ketamine, a non-competitive NMDA glutamate receptor antagonist, is typically used for procedural sedation and for induction of anesthesia. Given its potent glutamate antagonism, its use has gained popularity among pain specialists for maladaptive pain syndromes, such as Complex Regional Pain Syndrome (CRPS). Guidelines for the use of ketamine as an adjunct analgesic in acute pain are available, but appropriate dose, duration, and patient selection for chronic pain are still unclear.[117] Use of this agent should be supervised by clinicians experienced in its use.

Opioid Agents

① ⑦ ⑧ ⑨ ⑩ ⑪ Opioids are often the next step in the management of acute pain and cancer-related chronic pain (see Chapter 150 for use in cancer pain). This medication class may also be an effective treatment option in the management of chronic noncancer pain; however, this continues to be controversial. When a trial of opioids is warranted, it should follow a complete assessment of the pain complaint, an assessment of the patient's functionality goals, and risk factors for opioid use disorder or overdose.[118]

Opioid choice should be based on patient acceptance, analgesic effectiveness, as well as pharmacokinetic, pharmacodynamic, and adverse effect profiles with the attributes provided in Tables 79-5 and 79-12.[53,61]

TABLE 79-12

Dosing Guidelines

Agent(s)	Doses (Use Lowest Effective Dose, Titrate Up or Down Based on Patient Response, Opioid-Tolerant Patients May Need Dose Modification)	Notes
Morphine	PO 5-30 mg every 4 hours[1]	Medication of choice in severe pain
	IM 5-20 mg every 4 hours[1]	Use immediate-release product with SR product to control breakthrough pain in cancer patients
	IV 5-15 mg every 4 hours[1]	Typical patient controlled analgesia IV dose is 1 mg with a 10-minute lock-

		out interval
	SR 15-30 mg every 12 hours (may need to be every 8 hours in some patients)	Every 24-hour products available
	Rectal 10-20 mg every 4 hours[1]	
Hydromorphone	PO 2-4 mg every 4-6 hours[1]	Use in severe pain
	XR 8 mg to 64 mg every 24 hours	More potent than morphine; otherwise, no advantages
	IM 1-2 mg every 4-6 hours[1]	
	IV 0.5-2 mg every 4 hours[1]	Typical patient-controlled analgesia IV dose is 0.2 mg with a 10-minute lock-out interval
	Rectal 3 mg every 6-8 hours[1]	Every 24-hour product (Exalgo) available
Oxymorphone	IM 1–1.5 mg every 4-6 hours[1]	Use in severe pain
	IV 0.5 mg every 4-6 hours[1]	No advantages over morphine
	PO immediate-release 5-10 mg every 4-6 hours[1]	Use immediate-release product with controlled-release product to control breakthrough pain in cancer or chronic pain patients
	PO extended-release 5-10 mg every 12 hours[1]	Manufacturer recommends 5 mg every 12 hours in opioid-naïve patients
		Take ER on empty stomach
Levorphanol	PO 2-3 mg every 6-8 hours[1] (Levo-Dromoran)	Use in severe pain
	PO 2 mg every 3-6 hours[1] (Levorphanol Tartrate)	Extended half-life useful in cancer patients
	IM 1-2 mg every 6-8 hours[1]	In chronic pain, wait 3 days between dosage adjustments
	IV 1 mg every 3-6 hours[1]	
Codeine	PO 15-60 mg every 4-6 hours[1]	Use in mild-to-moderate pain
	IM 15-60 mg every 4-6 hours[1]	Weak analgesic; analgesic prodrug
Hydrocodone	PO 5-10 mg every 4-6 hours[1]	Use in moderate/severe pain
Oxycodone	PO 5-15 mg every 4-6 hours[1]	Use in moderate/severe pain
	Controlled release 10-20 mg every 12 hours	
		Use immediate-release product with controlled-release product to control

		breakthrough pain in cancer or chronic pain patients
		CR reformulated to deter unhealthy use
Meperidine	IM 50-150 mg every 3-4 hours[1]	Use in severe pain
	IV 5-10 mg every 5 minutes prn[1]	Oral not recommended
		Do not use in renal failure
		May precipitate tremors, myoclonus, and seizures
		Monoamine oxidase inhibitors can induce hyperpyrexia and/or seizures or opioid overdose symptoms
Fentanyl	IV 25-50 mcg/hours	Used in severe pain
	IM 50-100 mcg every 1-2 hours[1]	Do not use transdermal in acute pain
	Transdermal 25 mcg/hr every 72 hours	Transmucosal for breakthrough cancer pain in patients already receiving or tolerant to opioids
	Transmucosal (Actiq/OTFC Lozenge and Onsolis buccal film) 200 mcg may repeat × 1, 30 minutes after first dose is started, then titrate	Always start with lowest dose despite daily opioid intake; product-specific titration recommendations exist
	Transmucosal (Fentora Buccal Tablet) 100 mcg, may repeat × 1, 30 minutes after first dose is started, then titrate	
	Intranasal (Lazanda Spray) 100 mcg (one spray) in one nostril. Wait 2 hours prior to redosing	
	Sublingual (Subsys Spray) 100 mcg (1 spray). Wait 4 hours prior to redosing	
	Sublingual (Abstral Tablet) 100 mcg tablets placed sublingually. Must wait 2 hours prior to redosing	
Methadone	PO 2.5-10 mg every 8-12 hours[1]	Effective in severe chronic pain
	IM 2.5-10 mg every 8-12 hours[1]	
		Some chronic pain patients can be dosed every 12 hours
		Equianalgesic dose of methadone when compared with other opioids will decrease progressively the higher the previous opioid dose. Avoid dose titrations more frequently than weekly in chronic pain maintenance
Pentazocine	PO 50-100 mg every 3-4 hours[2] (max. 600 mg daily, for	Second-line agent for moderate-to-severe pain; may precipitate withdrawal

	those 50 mg tablet containing 0.5 mg of naloxone)	in patients with physical opioid dependence; parenteral doses not recommended
	PO 25 mg every 4 hours[2] (max. 150 mg daily, for those 25 mg tablet containing 325 mg of acetaminophen)	
Butorphanol	IM 1-4 mg every 3-4 hours[2]	Second-line agent for moderate-to-severe pain
	IV 0.5-2 mg every 3-4 hours[2]	May precipitate withdrawal in patients with physical opioid dependence
	Intranasal 1 mg (1 spray) every 3-4 hours[2]	
	If inadequate relief after initial spray, may repeat in other nostril × 1 in 60-90 minutes	
	Max. 2 sprays (one per nostril) every 3-4 hours[2]	
Nalbuphine	IM/IV 10 mg every 3-6 hours[2] (max. 20 mg dose, 160 mg daily)	Second-line agent for moderate-to-severe pain; may precipitate withdrawal in patients with physical opioid dependence
		Used frequently in low doses to treat/prevent opioid-induced pruritus
Buprenorphine	IM 0.3 mg every 6 hours[2]	Second-line agent for moderate-to-severe pain
	Slow IV 0.3 mg every 6 hours[2]	May precipitate withdrawal in patients with physical opioid dependence
		Transdermal delivery systems (5, 7.5, 10, 15, 20 mcg/hr) available for every 7 day administration. Detailed manufacturer dosing conversion recommendations exist
		Buccal delivery system (75, 150, 300, 450, 600, 750, and 900 mcg) available. Detailed manufacturer dosing conversion recommendations exist.
		Naloxone may not be effective in reversing respiratory depression
Tramadol	PO 50-100 mg every 4-6 hours[1]	Maximum dose for nonextended-release, 400 mg/24 hr; maximum for extended release, 300 mg/24 hr
	If rapid onset not required, start 25 mg/day and titrate over several days	Decrease dose in patient with renal impairment and in older patients
	Extended release PO 100 mg every 24 hours	
Tapentadol	PO 50-100 mg every 4-6 hours[1]	First day of therapy may administer second dose after the first within 1 hour maximum dose first day 700 mg, max. dose thereafter 600 mg (maximum dose for CR 500 mg)

[1] May start with an around-the-clock regimen and switch to prn if/when the painful signal subsides or is episodic.

[2] May reach a ceiling analgesic effect.

HCL, hydrochloride; IM, intramuscular; IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug; PO, oral; prn, as needed; SR, sustained release; OTFC, Oral transmucosal fentanyl citrate; CR, controlled release; XR, extended release; mcg, microgram; mg, milligram.

Data from References [53, 61,119].

The pharmacologic activity of opioids depends on their affinity for and action at one or more central and peripheral opiate receptors. These g-protein coupled receptors include mu (MOR), kappa (KOR), delta (DOR), and noceptin (OLR-1), which have variable physiologic effects. Therapeutic activities and adverse effects for this medication class range from those exhibited by the MOR agonists (eg, morphine) to those seen with the nonselective antagonists (eg, naloxone). Partial MOR agonists (eg, buprenorphine) and mixed MOR antagonists/KOR agonists (eg, nalbuphine) compete with agonists for opiate receptor sites. Depending on the inherent agonist and antagonist properties, these medications may precipitate opioid withdrawal and pain crisis if initiated in patients with physical MOR dependence or tolerance.[120] Additionally, patients stable on a partial or mixed MOR agonists may exhibit an attenuated response to pure MOR agonists when administered for pain. Efficacy and adverse effects also may further differ among opioid agents because of receptor subtype variability and partially explain why some patients respond differently to certain opioids, specifically MOR agonists.[121] Opioid antagonists may act centrally (eg, naloxone or naltrexone) or be limited to peripheral action only (eg, alyimopan, naloxegol, methylnaltrexone, or naldemedine) (Table 79-13).[61,122]

TABLE 79-13

Central and Peripheral Opioid Antagonists

Generic Name (Brand Name)	Activity	Role	Route	Dose in Adults (mg)	Special Considerations
Naldemedine (Symproic)	Peripheral	CNMP[a], OIC[b]	PO	0.2 mg qday	Avoid with severe hepatic impairment
Naloxone (Narcan, various) Methylnaltrexone (Relistor) Naltrexone (ReVia, Vivitrol) Alvimopan (Entereg) Naloxegol (Movantik)	Central Peripheral Central Peripheral Peripheral	Opioid reversal Cancer and CNMP[a] OIC[b] AUD,[c] OUD[d] Postoperative ileus CNMP[a], OIC[b]	IV, IM, IN SC (both), PO (CNMP) PO, IM PO PO	0.4-2 mg[e] Variable 12 mg Qday-Q12 (PO) 380 mg q4weeks (IM) 12 mg PO 30 minutes-5 hours before surgery then 12 mg PO BID starting day after surgery for maximum of 7 days 12.5-25mg qday 1 hour before, 2 hours after a meal	Onset 1-2 (IV) minutes, 2-5 (IM) minutes Half-life 0.5-1.3 h Renal dose adjustments Opioid free for 7-10 days before initiation Limited to 15 doses Renal dose adjustments Avoid with moderate 3A4 inhibitors

[a] Chronic nonmalignant pain.

[b] Opioid-induced constipation.

[c] Alcohol use disorder.

[d] Opioid use disorder.

[e] Starting doses to be used in cases of opioid overdose.

Data from individual package inserts.

The effects of the opioid analgesics are relatively selective and, at normal therapeutic concentrations, do not affect other sensory modalities.[9,120] While sensations of touch and proprioception are preserved, undesirable adverse effects may increase as the dose is escalated (Table 79-6).[9,120] Frequently, when opioids are administered, pain is not eliminated, but its unpleasantness is decreased. Patients report that although their pain is still present, it no longer bothers them.

⑧⑨Opioids share related pharmacologic attributes and exert a profound effect on the CNS and GI tract. Mood changes, sedation, nausea, vomiting, decreased GI motility, constipation, respiratory depression, physical dependence, pruritus, and tolerance are evident in varying degrees with all agents.[120] Tolerance to adverse effects (except to constipation) often develops over time. Some differences exist between the opioids in regards to incidence of adverse effects, which may assist in selection of the most appropriate agent.

⑦⑧⑨The route of administration depends on individual patient needs, with the oral route being preferred. However, the onset of analgesic effect for oral medications is approximately 45 minutes, and the peak effect usually occurs 1 to 2 hours after administration.[9,53] This delay must be considered when immediate relief is needed in the management of acute pain (ie, postsurgical or cancer breakthrough). Therefore, in some scenarios, such as acute severe pain (eg, pain crisis) or when the patient is unable to take oral medications, alternative routes of therapy, such as intravenous (IV) administration, may be preferred.[33] The relative potency, defined by the equianalgesic dose, of opioids differs greatly (Table 79-5). Equianalgesic dose tables are often based on single-dose studies without regard for patient variability and should be used only as a guide, with further dose titration frequently required.[53,119]

Although true opioid allergies are rare, Table 79-5 can also be used when treating a patient who has a documented hypersensitivity to opioids. Differing chemical classes of opioids may theoretically provide some reduction in cross reactivity when hypersensitivity is of concern. Most reactions, such as pruritus or rash, are either related to associated histamine release from cutaneous mast cells or activation of central MOR receptors and not a true allergic or immunoglobulin-E (IgE) or T-cell response.[123–125] Although caution is always advised, a decrease in potential cross-sensitivity is thought to exist when moving from one opioid structural class to another.[124] The classes are phenanthrenes (morphine-like agonists), benzomorphans (pentazocine), phenylpiperidines (fentanyl-like agonists), and diphenylheptanes (methadone-like agonists). When considering hypersensitivity cross-reactivity, the mixed agonist–antagonist and partial agonist class acts much like the morphine-like agonists.[125]

⑧⑨In the initial stages of acute pain, analgesics should be given around the clock. This should commence after administering a typical starting dose and titrating up or down, depending on the patient's degree of pain and demonstrated adverse effects (eg, sedation). As-needed schedules may produce wide swings in analgesic plasma concentrations resulting in alternating states of uncontrolled pain and sedation. This may initiate a vicious cycle where increasing amounts of pain medications are needed for relief. As the pain improves and the need for medication decreases, as-needed schedules may be appropriate, which may also be useful in patients who present with pain that is intermittent or sporadic in nature. When opioids are used in the management of chronic noncancer pain, around-the-clock administration schedules can be considered. While rare, as-needed immediate-release opioids may be used in conjunction with ER/LA opioids for times when patients experience significant breakthrough pain (Fig. 79-2). This practice is more common in treatment pain associated with cancer or its treatment.

⑦Continuous IV infusion of opioids should be reserved for opioid-tolerant patients.[126,127] An alternative method is patient-controlled analgesia (PCA), which is a technique by which patients can self-administer a preset dose of an IV opioid via a pump electronically interfaced with a timing device. Compared with traditional as-needed opioid dosing, PCA yields better pain control, improved patient satisfaction, and relatively few differences in adverse effects.[126,128]

Administration of opioids directly into the CNS (eg, epidural and intrathecal/subarachnoid routes) may also be used by anesthesiology pain consult services in the control of acute, chronic noncancer, and cancer pain and is useful in more difficult to control pain states (Table 79-14).[129,130]

TABLE 79-14

Intraspinal Opioids

Agent	Single Dose (mg)	Onset of Pain Relief (min)	Duration of Pain Relief (hr)	Continual Infusion Dose (mg/hr)
Epidural route				
Morphine	1-6	30	6-24	0.1-1
Hydromorphone	0.8-1.5	5-8	4-8	0.1-0.3
Fentanyl	0.025-0.1	5	2-8	0.025-0.1
Sufentanil	0.01-0.06	5	2-4	0.01-0.05
Subarachnoid route				
Morphine	0.1-0.3	15	8-34	–
Fentanyl	0.005-0.025	5	3-6	–

Doses above should not be interpreted as equianalgesic doses for conversion to or from the specific opioid or route of administration.

Data from References [53, 61,130].

⑧ Due to reports of respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension, these methods of analgesia require careful monitoring and are best used by experienced practitioners. Respiratory depression is of concern and can occur within minutes after intrathecal fentanyl or manifest as late as 19 hours after a single dose of intrathecal morphine. Guidelines mandate respiratory monitoring for at least 24 hours after a single dose of intrathecal or epidural morphine with standing orders for naloxone (opioid antagonist) for full or partial reversal.[126,127] Analgesia and adverse effects are evident at even lower doses when opioids are administered intrathecally instead of epidurally. This form of analgesia is often administered as a continuous-infusion and/or on a patient-controlled basis. When given simultaneously with intrathecal or epidural local anesthetics such as bupivacaine, opioid analgesics have been proven relatively safe and effective. All agents administered directly into the CNS should be preservative free.

Full Mu Opioid Receptor Agonists

⑥ ⑩ Despite the availability of several newer agents, morphine remains the prototype opiate analgesic. As new opioid and nonopioid compounds are developed, their efficacy and adverse-effect profiles are typically compared against morphine as the standard. Using equianalgesic tables, clinicians often refer to "oral morphine equivalents" when describing efficacy or risk of harms of other opioids.[37,119] Many clinicians consider morphine the first-line agent when treating moderate-to-severe pain due to its relative low cost, broad clinical experience, and abundant dosage forms/strengths.

Adverse effects can be numerous, particularly when morphine is first initiated or when doses are significantly increased. Morphine causes nausea and vomiting through direct stimulation of the chemoreceptor trigger zone, decreased peristalsis, and a vestibular mechanism.[120] Opioid-induced nausea typically subsides over time with continued dosing, although this adverse effect may be incredibly troublesome to patients, especially following surgery.[131] As doses of morphine are increased, the respiratory center becomes less responsive to carbon dioxide, causing progressive respiratory depression.[9] This effect is more pronounced with concurrent administration with other respiratory depressants.[132] Respiratory depression often manifests as a decrease in respiratory rate (although minute volume and tidal exchange also are affected).[120] End-tidal capnography has become commonplace as a means to monitor opioid-induced respiratory depression, especially in those at increased risk.[133]

⑩ ⑪Opioid-induced respiratory depression can be rapidly reversed by the opioid antagonist, naloxone.[120] In patients with underlying pulmonary dysfunction or sleep disordered breathing, caution must be exercised when opioids are used, as these patients are already using compensatory breathing mechanisms and are at risk for further respiratory compromise.[134] Caution is also urged when combining opiate analgesics with alcohol or other CNS depressants (ie, benzodiazepines, SMRs, and sleep hypnotics), because this combination is potentially harmful and possibly lethal.[37]

Therapeutic doses of morphine have minimal effects on blood pressure, cardiac rate, or cardiac rhythm when patients are supine; however, morphine does produce venous and arteriolar vessel dilation, potentially resulting in orthostatic hypotension, and hypovolemic patients may be more susceptible to morphine-induced cardiovascular changes (eg, decreases in blood pressure).[9] Because morphine prompts a decrease in myocardial oxygen demand in ischemic cardiac patients, it is often used to treat pain associated with myocardial infarction, although this practice has been called into question due to the potential for increased mortality.[135]

Morphine decreases the propulsive contractions of the GI tract resulting in constipation. Morphine-induced spasms of the sphincter of Oddi have also been observed; however, the clinical significance of this is unclear. Urinary retention is another significant adverse effect of morphine and should be routinely assessed. Morphine-induced histamine release often manifests as pruritus and may even exacerbate bronchospasm in patients with a history of asthma.[53] Therapeutic doses of morphine are not contraindicated in head injury, but medication-induced respiratory depression can increase intracranial pressure. Thus, caution is advised in head trauma patients who are not mechanically ventilated because morphine may increase intracranial pressures and cloud the neurologic examination results.[120]

Morphine is metabolized to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). Whereas M6G contributes to analgesia, M3G may contribute to unwanted neurologic adverse effects. The metabolites are renally cleared and can accumulate in patients with renal impairment, contributing to greater adverse effects.[120] Most clinicians recommend avoiding morphine in renally compromised patients (ie, creatinine clearance ≤30 mL/minute [0.50 mL/s]). Morphine also inhibits the release of gonadotropin-releasing hormone from the hypothalamus, thus decreasing plasma testosterone and cortisol (opioid-induced hypogonadism). Male patients may present with symptoms of erectile dysfunction, decreased libido, and decreased analgesic efficacy. Females may experience alopecia, amenorrhea, and depressed mood, as well as decreased analgesic efficacy. Recommendations for clinical replacement of these hormones in patients using chronic opioid therapy are not well defined.[136] While the clinical meaning has not clearly been elucidated, morphine and other opioids, depending on the situation being used, may either enhance or inhibit the immune system.[53,120]

Hydromorphone is more potent than morphine, but its overall pharmacologic profile is similar. Some clinicians believe hydromorphone is associated with fewer adverse effects, especially pruritus, compared with other opioids. However, the research is limited and does not conclusively demonstrate this difference. Oxymorphone is available both orally and parenterally, although it offers no pharmacologic advantage over morphine. Levorphanol has an extended half-life and purported NMDA glutamate receptor activity, but its overall therapeutic effects are similar to the other agents in this class and cost is frequently a barrier to its use.[137,138]

Codeine is a commonly used opioid for the treatment of mild-to-moderate pain. It often is combined with other analgesic products (eg, acetaminophen). Unfortunately, it has the propensity to produce the adverse effects as morphine. Due to the risk of toxicity in patients with rapid metabolizer phenotypes, the FDA recommends against codeine's use in children and, in particular, infants being fed human milk.[139] Hydrocodone is perhaps the most commonly prescribed opioid in the United States and is available orally as immediate-release combined with nonopioid analgesics, as well as extended-release formulations. Its pharmacologic properties are similar to those of morphine. Oxycodone is a useful oral analgesic for moderate-to-severe pain. This is especially true when the product is used in combination with nonopioids. Although oxycodone shares basic morphine characteristics, the availability of an immediate-release and controlled-release oral dosage form also makes it very useful in chronic pain as well as cancer pain. Oliceridine, a novel opioid analgesic medication approved for IV use for moderate-severe pain, is classified as a biased opioid agonist. It displays selective mu opioid receptor agonism and is structurally dissimilar from other opioid analgesics. Oliceridine is associated with fewer tolerability concerns than traditional opioids; however, more literature is needed to support this claim. The prototype phenylpiperidine, meperidine, has a pharmacologic profile comparable with that of morphine; however, it is not as potent and has a shorter analgesic duration. Meperidine offers no analgesic advantage over morphine, has greater toxicity (CNS hyperirritability caused by its renally-eliminated metabolite normeperidine), and should be limited in use, especially in older patients, those with renal dysfunction, or for prolonged treatment durations.[53,140]

Fentanyl is a synthetic opioid structurally related to meperidine but is significantly more potent and faster acting. It can be administered parenterally, transmucosally, sublingually, intranasally, and transdermally.[9,120] Numerous fentanyl-like agents exist including remifentanil, alfentanil, and sufentanil. Remifentanil and alfentanil are limited to use as part of general anesthesia, whereas sufentanil can be used for acute pain as a sublingual tablet in medically supervised settings.[141]

Methadone is a useful analgesic due to its oral efficacy, extended duration of action, and low cost. Properties unique to methadone, compared with other opioids, include the S-isomer's ability to antagonize NMDA receptors, agonist effects at the kappa and delta opioid receptor, as well as the blockade of serotonin and norepinephrine reuptake.[120,142] These properties may prove useful in the treatment of neuropathic and chronic pain. However, few trials have thoroughly evaluated methadone's risks versus benefits.[142,143] Epidemiologic studies suggest an increased number of methadone-related deaths, and cardiac arrhythmias have been associated with this medication, particularly at higher doses or when used concurrently with other agents that prolong QTc intervals.[132] Recommendations exist for specific echocardiogram monitoring for methadone.[143] The equianalgesic dose of methadone may decrease with higher doses of the comparator opioid, complicating conversions from other opioids to methadone. Methadone should not be titrated more frequently than every 5 to 7 days due to its unpredictable potency and variable half-live.[143] Thus, given the risks, methadone should be reserved to specialists with experience in it use.

Mixed Opioid Agonist–Antagonists

This analgesic class produces analgesia and has the potential for less respiratory depression than opioid agonists as they exert their analgesic activity via the KOR and either block or act as partial agonists at the MOR.[120] Agents in this class are considered to less physical dependence than morphine, but psychotomimetic responses (eg, hallucinations and dysphoria), limited analgesic effect, and a potential to initiate withdrawal in opioid-dependent populations have precluded their widespread clinical use. Both butorphanol and nalbuphine are available parenterally, with butorphanol also available as an intra-nasal spray. Nalbuphine is gaining popularity as a treatment for MOR agonist–associated pruritus.[144]

Buprenorphine is a pharmacologically complex opioid, which exhibits KOR antagonism, and several MOR-related actions, including partial agonism. Buprenorphine also displays agonist properties at the opioid receptor-like 1 (ORL-1) receptor which may have clinical ramifications in prevention of tolerance, euphoria/reward, and hyperalgesia.[145] Buprenorphine is available as a sublingual tablet, a buccal film, a once-weekly transdermal patch, or in combination with naloxone as a sublingual film or sublingual tablet. While buprenorphine's use for opioid use disorder previously required a special DEA license to prescribe, practitioners may now bypass this training requirement and obtain a waiver under the Controlled Substances Act by submitting a letter of intent to the Substance Abuse and Mental Health Services Administration (SAMHSA). The decrease in requirements for prescribing buprenorphine for OUD expands access to treatment.[146]

Central-Acting Opioids

Tramadol and tapentadol are the only centrally acting opioids available in the United States. Tramadol binds to MOR receptors and inhibits the reuptake of serotonin, and to a lesser extent, norepinephrine.[147] Tapentadol also binds the MOR receptor, but inhibits largely norepinephrine reuptake. Tramadol is indicated for the relief of moderate to moderately severe pain, while tapentadol is indicated for moderate-to-severe acute pain and diabetic peripheral neuropathy.

Both tramadol and tapentadol have adverse effect profiles similar to that of the previously mentioned opioid analgesics (eg, dizziness, nausea, somnolence, and constipation). Tapentadol has not been systematically evaluated in patients with seizures, and it should be used with caution. Seizure risk, as well as risk of hypoglycemia and hyponatremia, may be elevated in patients taking tramadol.[147,148] Tramadol may have a place in treating patients with chronic pain, especially neuropathic pain, while tapentadol may be useful in the management of acute pain and the controlled release product may have a role in chronic pain treatment (eg, diabetes-related nerve pain).[149,150] Tapentadol is also associated with less physical dependence over time when compared with morphine and pentazocin.[151]

Opioid Antagonists

⑪The opioid antagonist naloxone binds competitively to opioid receptors but does not produce an analgesic or opioid adverse effect response. Therefore, it is used most often to reverse the toxic effects of agonist- and agonist–antagonist-derived opioids. Other opioid antagonists exist, including naltrexone, naloxegol, naldemedine, and methylnaltrexone. Naltrexone's use is primarily limited to substance use disorder treatment, while naloxegol, naldemedine, and methylnaltrexone are peripherally acting only and used for opioid-induced constipation.[122]

⑪With the growing prevalence of heroin and fentanyl analogs overdoses, healthcare providers are increasingly being called upon to assist in the prevention of these deaths. Many states have legislation in place that allow pharmacists to provide expanded access to naloxone which may be administered intranasally in addition to the traditional intravenous or intramuscular formations.[152] Further discussion of naloxone education, administration, and monitoring is provided in Chapter 85, "Substance-Related Disorders: Overview and Depressants, Stimulants, and Hallucinogens."

Tolerance, Hyperalgesia, Physical Dependence, and Opioid Use Disorder

①②③④⑪A barrier that consistently causes clinicians to misjudge and mistreat pain is the misunderstanding of opioid tolerance, hyperalgesia, and physical dependence. Tolerance is the reduction of medication effect over time as a result of exposure to the agent.[120] It develops at different rates and with great patient variability. However, with stable disease, opioid doses may stabilize over time. Hyperalgesia is an increased sensitivity to pain. Opioids have been implicated in contributing to this phenomenon and can be seen with rapid opioid escalation or high-dose administration.[153] The mechanism or true clinical impact of this phenomenon is not understood.

Opioid physical dependence is characterized by an abstinence syndrome following administration of an antagonist medication or abrupt dose reduction or discontinuation of an opioid.[120,121] Clinicians must understand that physical dependence and tolerance are not equivalent to substance use disorder, and with chronic opioid use, physical dependence is expected.[121]

A baseline assessment and ongoing evaluation of patient behaviors is critical to mitigate risks of chronic opioid therapy and to balance effective pain management and patient safety.[154,155] Risk for opioid use disorder is associated with a family history of a substance use disorder, and/or underlying psychiatric diagnoses. Modifications to the treatment plan, which should be stratified based on patient risk, include baseline and random urine toxicology results, patient–provider treatment agreements, pill counts, a smaller prescription supply, and regular assessment of use behaviors. Table 79-7 outlines the CDC's guidelines to assist clincians.[156] Combining these approaches with regular and ongoing assessments of pain and functionality may result in improved outcomes. Chapter e84, "Introduction to Substance Use Disorders" contains additional information.

Multimodal Therapy

④⑤⑥Commonly, multimodal therapy may be employed to optimize either acute or chronic pain management. Multimodal therapy is the concomitant use of different therapeutic interventions with the intent of obtaining additive therapeutic effects. Multimodal analgesia, one type of multimodal therapy, includes combining medications from different analgesic classes (eg, combination therapy with opioids and nonopioids or co-analgesics).[9,121] This often results in analgesia superior to that produced by either agent alone. Multimodal analgesia may also permit the use of lower doses and provide a more favorable adverse-effect profile, for example when NSAIDs are prescribed with opioids yielding an "opioid sparing" effect.

Regional Analgesia

⑦⑨Regional analgesia with properly administered local anesthetics can provide relief of both acute and chronic pain (Table 79-15).[130,157,158] These agents can be positioned by injection (eg, in joints, in the epidural or intrathecal space, along nerve roots, or in a nerve plexus) or topically. Lidocaine in the form of a patch has proven effective in treating focal neuropathic pain.[65] Regional nerve blocks with local anesthetics may effectively relieve pain. Although rare, elevated plasma concentrations of local anesthetics can cause CNS-excitation and depression, including dizziness, tinnitus, drowsiness, disorientation, muscle twitching, seizures, and respiratory arrest.[157] This syndrome is called LAST (local anesthetic systemic toxicity).[159] Cardiovascular adverse effects include myocardial depression, hypotension, decreased cardiac output, heart block, bradycardia, arrhythmias, and cardiac arrest. Disadvantages of such methods include the need for skillful technical application, need for frequent administration, and highly specialized follow-up procedures.

TABLE 79-15

Local Anesthetics[a]

Agent (Brand Name)	Onset (min)	Duration (h)
Esters		
Procaine (Novocain, various)	2-5	0.25-1
Chloroprocaine (Nesacaine, various)	6-12	0.5
Tetracaine (Pontocaine)	≤15	2-3
Amides		
Mepivacaine (Polocaine, various)	3-5	0.75-1.5
Bupivacaine (Marcaine, various)	5	2-4
Bupivacaine liposomal (Exparel—wound infiltration only)	variable	24 local 96 systemic
Lidocaine (Xylocaine, various)	<2	0.5-1
Prilocaine (Citanest)	<2	1-2
Ropivacaine[b] (Naropin)	10-30	0.5-6

[a] Unless otherwise indicated, values are for infiltrative anesthesia.

[b] Epidural administration.

TABLE 79-16

Topical Analgesics

Medication	Uses	Mechanism of Action	Dosing	Notes
Capsaicin cream (various)	Temporary relief of minor aches and pains of muscles and jointsLocalized neuropathic pain	Transient receptor potential vanilloid 1 (TRPV1) receptor agonist	Apply 3-4 times daily	Continue scheduled use for 2-4 weeks for best results

Capsaicin 8% patch (Qutenza)	PHN, DPN	Transient receptor potential vanilloid 1 (TRPV1) receptor agonist	• Apply 1-4 patches to affected area for 60 minutes (PHN) or 30 minutes (DPN) • Cleansing gel must be used on application site following patch removal • Repeat no more frequently than q3 months • Max: 4 patches	• Administer under supervision of physician • Specific administration directions in packaging information • Apply topical anesthetic before applying • Monitor blood pressure due to transient increase in blood pressure during application
Diclofenac 1% gel (Voltaren)	Pain of osteoarthritis of joints amenable to topical treatment (knees, hands)	Nonsteroid anti-inflammatory drugs (NSAIDs)	• Lower extremities: 4 g QID, max 16 g/day • Upper extremities: 2 g QID, max 8 g/day • Total dose maximum: 32 g/day	• Same black box warnings as PO NSAIDs despite low systemic bioavailability (6% of systemic exposure from oral diclofenac) • Use dosing card to measure amount
Diclofenac epolamine 1.3% patch (Flector)	Topical treatment of acute pain due to minor strains, sprains, and contusions	NSAIDs	1 patch to most painful area BID	Systemic effects were <1% after 4 days of repeated dosing
Diclofenac topical solution (Pennsaid)	Pain from osteoarthritis of the knee	NSAIDs	1.5%: 40 drops to each affected knee 4 times daily. Apply 10 drops at a time 2%: 2 pumps (40 mg) on each painful knee BID	Same black box warnings as PO NSAIDs
Lidocaine gel/ointment/patch (various)	Neuropathic pain	Sodium channel blocker	Cream/ointment: Apply to affected area 3 times dailyPatch: apply 1 patch to affected area up to 12 h	Apply to intact skin only
Lidocaine 5% patch (Lidoderm, also available in 4% over the counter)	PHN	Sodium channel blocker	Apply 1-3 patches to site of pain for 12 hMaximum: 3 patches	May cut lidocaine patches Apply to intact skin only Severe hepatic impairment increases risk of adverse effects
Menthol/methyl salicylate (various)	Minor aches and pains of muscles and joints (simple backache, arthritis, strains, bruises, sprains)	Rubefacient	Apply topically 3-4 times a day to affected area	
Trolamine salicylate cream 10% (various)	Aches and pains of muscles and joints (arthritis, simple backache, bruises, sprains, strains)	Rubefacient	Apply topically 3-4 times a day to affected area	Do not apply to damaged skin

Data from Reference [61].

SPECIAL POPULATIONS

⑥ ⑨ Some patients are at a higher risk for under-treatment because of potential inability to communicate or rate their pain (eg, infants, noncommunicative adults, or those with dementia). It is in these cases that parent or caregiver input becomes paramount to identify changes in behavior, which might suggest pain (eg, fussy, inconsolable, changes in eating patterns, crying out, or agitation). When patients cannot verbalize their pain (eg, coma), monitoring behaviors (eg, agitation) and physiologic signs and symptoms (eg, heart rate) are appropriate. Validated pain assessment tools are available to assist the clinician in approaching patients who are unable to readily communicate the severity of their pain.[160]

In addition, those living with chronic, debilitating, and life-threatening illnesses need specialized pain control and care that is palliative in nature.[158] Although care must be taken in these populations to ensure that proper individualized treatment plans follow accepted guidelines, the key concepts in pain management as outlined in this chapter are the guiding tenets in maximizing pain control.[161,162]

PERSONALIZED PHARMACOTHERAPY

⑥ ⑧ ⑨ Pharmacogenomics is one factor that can impact medication response, and pharmacogenomic differences can contribute both to a lack of response (analgesia) and toxicity (adverse effects).[163] Guidance is available for prescribing and dosing certain NSAIDs, opioids, and antidepressants that are used in pain management when pharmacogenomic information is available.[63,90,164] However, guidance is not available on when to use pharmacogenomic testing in pain management as it is nota routine practice. Pharmacogenomic testing may be considered in polypharmacy, high risk patients, potential for significant adverse effects, and medications with specific dosing considerations.[165,166]

Several NSAIDs are metabolized by CYP2C9 and impacted by pharmacogenomic variability. NSAIDs involved include celecoxib, flurbiprofen, ibuprofen, meloxicam, and piroxicam. Those that are intermediate or poor metabolizers of CYP2C9 are at increased risk of adverse effects due to reduced metabolism. Dosing recommendations vary depending on the phenotype, from use of standard doses to initiation at lower doses or use of alternate NSAIDs not metabolized through CYP2C9 like aspirin, ketorolac, naproxen, or sulindac.[63]

Tricyclic antidepressants are metabolized by CYP2D6 and CYP2C19. While CPIC guidelines exist for TCAs, they are geared toward TCA use in the management of depression, not pain. Since TCAs, when used in pain management, are used at lower doses than used for depression, those that are poor or intermediate CYP2D6 or CYP2C19 metabolizers are less likely to encounter adverse effects, so dose adjustments are not recommended. However, if higher doses of amitriptyline are used for managing pain than the recommendations for depression should be considered.[90]

Other antidepressants used in the management of pain are either partially or significantly metabolized by CYP2D6 though have less clear pharmacogenomic guidance. Duloxetine is metabolized more so by CYP1A2, with some contribution by CYP2D6 to hydroxy metabolites. Venlafaxine is metabolized by CYP2D6 to O-desmethylvenlafaxine. Guidance from the Royal Dutch Association for the Advancement of Pharmacy do not recommend any dose adjustments for duloxetine based on pharmacogenomics as it is not a gene-drug interaction.[167] For venlafaxine in intermediate and poor CYP2D6 metabolizers, there is unclear information if there is an increased risk of adverse effects and thus no firm guidance on how to adjust the dose is provided; alternate recommendations include the use of an alternate antidepressants not impacted by CYP2D6.[168] In CYP2D6 ultrarapid metabolizers, the dose of venlafaxine can be increased by 150% the standard dose; however, if dose adjustment is not effective or leads to adverse effects, then venlafaxine should be avoided.

For patients of Asian ancestry, the FDA recommends testing for *HLA-B*15.02* and HLA-A*31.01 prior to initiation of carbamazepine and *HLA-B*15.02* before starting oxcarbazepine due to the increased risk for life-threatening dermatologic reactions including Steven–Johnson Syndrome (SJS)/toxic epidermal necrolysis (TEN), drug reaction with eosinophilia and systemic symptoms (DRESS), and maculopapular exanthema (MPE). Those with *HLA-B*15.02* and/or *HLA-A*31.01* positive genotyping should not be started on carbamazepine or if *HLA-B*15.02* do not initiate oxcarbazepine if naïve. Severe dermatologic reactions usually occur within the first 3 months, so if a patient used carbamazepine for 3 months without issue, it can be considered in those that are *HLA-B*15.02* positive or *HLA-A*31.01* positive.[164]

CPIC guidelines cover CYP2D6, mu opioid-receptor-1 (OPRM1), and catechol-o-methyltransferase (COMT) consideration with specific opioids.[169] Codeine and tramadol are both metabolized by CYP2D6 to active metabolites which are responsible for their analgesic and adverse effects. In CYP2D6 rapid metabolizers, codeine and tramadol should be avoided due to increased formation of their active forms contributing to significant adverse effects including respiratory depression. For CYP2D6 poor metabolizers, codeine and tramadol should be avoided to the potential for lack of analgesic benefit. Hydrocodone has less evidence supporting need for dose adjustment in CYP2D6 ultrarapid metabolizers compared to codeine and tramadol. There is some evidence showing decreased metabolism of hydrocodone to hydromorphone in CYP2D6 poor metabolizers but no specific dose adjustments are recommended. Oxycodone and methadone are not thought to be impacted significant by CYP2D6, so no recommendations are provided.

In some cases, genotype results may further help explain cases where patients require higher doses to achieve adequate analgesia. For example, data suggest that variants in opioid-receptor subtypes, specifically MOR-1 (OPRM1 gene), may predict efficacy and dosing requirements for some opioids such as morphine or hydromorphone.[170–172] CPIC does not provide recommendations based on COMT or OPRM1 genotypes.[169]

Use of pharmacogenomic testing results may be beneficial in the accurate interpretation of urine toxicology test results when assessing adherence to chronic opioid therapy. For instance, results from a urine toxicology report reveals only parent medication and no expected metabolites, which may be explained by medication interactions, CYP poor metabolizer phenotype, or diversion (pill shaving).

For more information regarding specific medication gene pairs related to pharmacogenomics, CPIC provides evidence-based peer-reviewed guidelines on interpretation of these testing results (www.cpicpgx.org).

EVALUATION OF THERAPEUTIC OUTCOMES

⑧Consistent monitoring for effectiveness (eg, pain relief, adequate functionality) and adverse effects (eg, sedation) is critical in optimizing therapeutic outcomes. Numerous validated scoring tools exist (eg, numeric rating scale, visual analog scale); however, the tools need to be appropriate for the type of pain being evaluated, used consistently, and with good clinical judgment.[28,34] Pain management efficacy, any change in pain, and medication adverse effects (eg, opioid-induced sedation or constipation) must be assessed and reassessed on a regular basis. Frequency of reassessment should be dictated by the medication's route of administration, duration of action, various pharmacokinetic factors, or other concomitant therapies. Postoperative pain and acute exacerbation of cancer pain may need to be assessed hourly or even more frequently, whereas chronic noncancer pain may require only daily or less frequent assessment. Pain intensity assessment is vital in acute pain, whereas functionality becomes more of an issue in chronic pain. Quality of life must be assessed on a regular basis in all patients. Many advocate for using the five "A's" (analgesia, activity, aberrant drug behavior, adverse effects, affect) as key assessment measures for any patient with chronic pain.

Often, objective signs are lacking for pain evaluation. Acute pain may result in increased sympathetic tone (eg, hypertension, tachycardia, and tachypnea); however, this response is usually diminished as acute pain progresses to chronic pain. The clinician must rely on the patient's description of their pain.

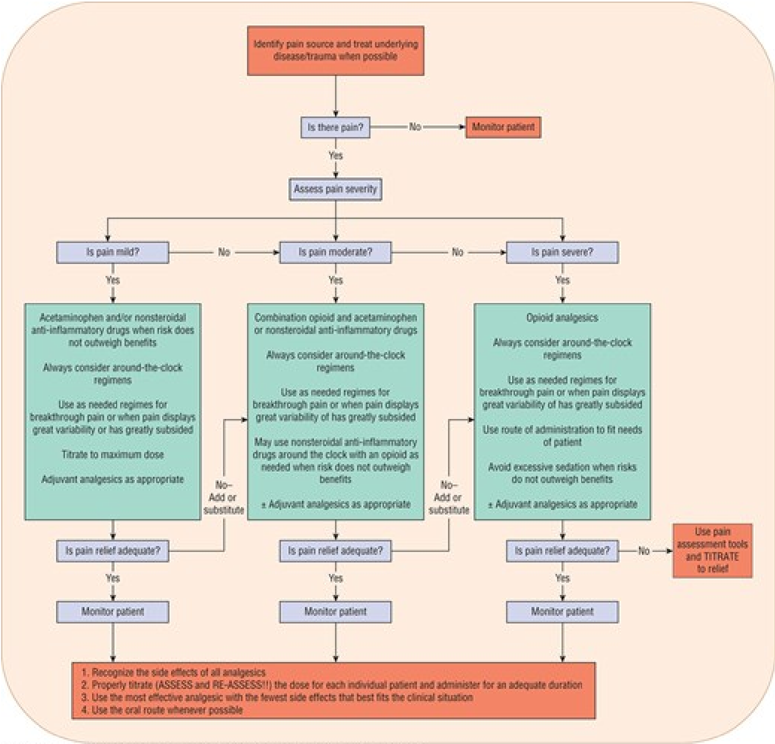
⑧⑨All opioids can cause constipation. The best management of constipation is prevention and patients should be counseled on the proper intake of fluids and fiber. A stimulant laxative with or without a stool softener should be added with chronic opioid use. For constipation that doesn't respond to standard bowel regimens, peripherally acting mu-opioid receptor antagonists (PAMORAs) are available for treating opioid-induced constipation. All CNS depressants (eg, alcohol, benzodiazepines) amplify CNS depression when used with opioid analgesics, and use of these combinations should be discouraged when possible. When the combinations are used, patients should be monitored closely.

CONCLUSION

Pain represents a significant source of disability as well as healthcare resource utilization. A thorough understanding of pain pathogenesis is imperative for clinicians involved in its treatment. Multidisciplinary and multimodal approaches to pain management must be considered with nonpharmacological and nonopioid modalities preferred as first-line treatments. Opioid analgesics are important analgesic alternatives and should be considered after careful patient selection. Monitoring for the occurrence of a substance use disorder while these agents are employed is essential. Adverse effects of all pharmacologic therapy for pain require judicious anticipation and treatment (Fig. 79-2).

FIGURE 79-2

Algorithm for acute pain. *(Adapted from Omnicare, Inc., Acute Pain Pathway.)*



Identify pain source and treat underlying disease/trauma when possible
Is there pain?
No
Monitor patient
Yes
Assess pain severity
Is pain mild?
No
Is pain moderate?
No
Is pain severe?
Yes
Yes
Yes
Acetaminophen and/or nonsteroidal anti-inflammatory drugs when risk does not outweigh benefits
Always consider around-the-clock regimens
Use as needed regimes for breakthrough pain or when pain displays great variability or has greatly subsided
Titrate to maximum dose
Adjuvant analgesics as appropriate
Combination opioid and acetaminophen or nonsteroidal anti-inflammatory drugs
Always consider around-the-clock regimens
Use as needed regimes for breakthrough pain or when pain displays great variability of has greatly subsided
May use nonsteroidal anti-inflammatory drugs around the clock with an opioid as needed when risk does not outweigh benefits
± Adjuvant analgesics as appropriate
Opioid analgesics
Always consider around-the-clock regimens
Use as needed regimes for breakthrough pain or when pain displays great variability of has greatly subsided
Use route of administration to fit needs of patient
Avoid excessive sedation when risks do not outweigh benefits
± Adjuvant analgesics as appropriate
No–
Add or substitute
No–
Add or substitute
Is pain relief adequate?
Is pain relief adequate?
Is pain relief adequate?
No
Use pain assessment tools and TITRATE to relief
Yes
Yes
Yes
Monitor patient
Monitor patient
Monitor patient
1. Recognize the side effects of all analgesics
2. Properly titrate (ASSESS and RE-ASSESS!!) the dose for each individual patient and administer for an adequate duration
3. Use the most effective analgesic with the fewest side effects that best fits the clinical situation
4. Use the oral route whenever possible
